1. INTRODUCTION

1.1 Background
The European Association of Urology (EAU) Guidelines Group for Urological Trauma prepared this guidelines document to assist medical professionals in the management of urological trauma.

The Urological Trauma guidelines are based on a review of the literature, using on-line searches of MEDLINE and other source documents published between 2005 and 2008. A critical assessment of the findings was made, not involving a formal appraisal of the data. There is a paucity of high-powered randomised controlled trials in this area and considerable available data are based on retrospective studies. The panel recognises this limitation.

A level of evidence (LE) and/or grade of recommendation (GR) have been assigned where possible (1). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

Publication history information: The Urological Trauma Guidelines were first published in 2003, with a partial update in 2006 followed by this full text update in 2009. Additionally, a quick reference guide is available. All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/online-guidelines/.

2. RENAL TRAUMA

2.1 Background
Renal trauma occurs in approximately 1-5% of all trauma cases (1,2). The kidney is the most commonly injured genitourinary and abdominal organ. There is a 3:1 male to female ratio in kidney trauma patients (3-5). Renal trauma can be acutely life-threatening, but the majority of renal injuries can be managed conservatively. Advances in imaging and treatment strategies during the past 20 years have decreased the need for surgical intervention and increased renal preservation (6-8).
2.2 Mode of injury

Renal injuries are classified by their mechanism: blunt or penetrating. In rural settings, blunt trauma can account for the largest percentage (90-95%) (9), while in urban settings the percentage of penetrating injuries can increase to 20% (6) or higher.

Blunt trauma is usually caused by motor vehicle accidents, falls, vehicle-associated pedestrian accidents, contact sports, and assault. Traffic accidents are the major cause of almost half the blunt renal injuries (10). Renal injury in frontal and side-impact collisions appears to occur after direct impact from objects in the vehicle compartment. For frontal crashes, occupant acceleration into the seat belt or steering wheel seems to result in renal injuries. Side impact injuries occur when the vehicle side panel intrudes into the compartment, striking the occupant (11). A 20-year review of renal injuries following free falls found a rate of 16% (12).

Renal lacerations and renal vascular injuries make up only 10-15% of all blunt renal injuries. Isolated renal artery injury following blunt abdominal trauma is extremely rare, and accounts for less than 0.1% of all trauma patients (13).

Renal artery occlusion is associated with rapid deceleration injuries. In theory, the kidney is displaced causing renal artery traction; the resulting tear in the inelastic intima and subsequent haemorrhage into the vessel wall leads to thrombosis. Compression of the renal artery between the anterior abdominal wall and the vertebral bodies may result in thrombosis of the renal artery.

Gunshot and stab wounds represent the most common causes of penetrating injuries. Renal injuries from penetrating trauma tend to be more severe and less predictable than those from blunt trauma. Bullets, because of their higher kinetic energy, have the potential for greater parenchymal destruction and are most often associated with multiple-organ injuries (14).

In wartime, the kidney is the most commonly injured urogenital organ. Most are found to be associated with major abdominal injuries, and the rate of wartime nephrectomies is relatively high (25-33%) (15-17).

2.2.1 Injury classification

Classifying renal injuries helps to standardise different groups of patients, select appropriate therapy, and predict results. A total of 26 classifications for renal injuries have been presented in the literature in the past 50 years (18), but the committee on organ injury scaling of the American Association for the Surgery of Trauma (AAST) has developed a renal-injury scaling system that is now widely used (19). Renal injuries are classified as grade 1 to 5 (Table 3). Abdominal computed tomography (CT) or direct renal exploration is used to classify injuries. Most recent publications in the field of renal trauma have adopted this classification. In a retrospective review, the AAST scaling system was determined as the most important variable predicting the need for kidney repair or removal (20,21). It also predicts for morbidity after blunt or penetrating injury, and for mortality after blunt injury (22).

|        | • Vascular: renal pedicle or avulsion |

*Advance one grade for bilateral injuries up to grade 3.
2.3 Diagnosis: initial emergency assessment

Initial assessment of the trauma patient should include securing the airway, controlling external bleeding, and resuscitation of shock, as required. In many cases, physical examination is carried out during the stabilisation of the patient. When renal injury is suspected, further evaluation (CT scan, laparotomy) is required for a prompt diagnosis.

2.3.1 History and physical examination

A direct history is obtained from conscious patients. Witnesses and emergency personnel can provide valuable information about unconscious or seriously injured patients. Possible indicators of major renal injury include a rapid deceleration event (fall, high-speed motor vehicle accidents) or a direct blow to the flank. In assessing trauma patients after motor vehicle accidents, the history should include the vehicle’s speed and whether the patient was a passenger or pedestrian.

In penetrating injuries, important information includes the size of the weapon in stabbings, and the type and calibre of weapon used in gunshot wounds, as high-velocity projectiles have the potential to cause more extensive damage.

The medical history should be as detailed as possible, as pre-existing organ dysfunction can have a negative effect on trauma patient outcome (23). In the early resuscitation phase, special consideration should be given to pre-existing renal disease (24). Another point of interest is the functioning renal mass of the trauma patient, as there are numerous case reports in the literature about complicated renal trauma in solitary kidneys (25).

Pre-existing renal abnormality makes renal injury more likely following trauma. Pre-existing renal pathology should be noted. Hydronephrosis due to ureteropelvic junction abnormality, renal calculi, cysts, and tumours are the most commonly reported entities that may complicate a minor renal injury (26). The overall percentage of these cases varies from 4% to 22% (27,28).

Haemodynamic stability is the primary criterion for the management of all renal injuries. Shock is defined as a systolic blood pressure of less than 90 mmHg found at any time during an adult patient’s evaluation. Vital signs should be recorded throughout diagnostic evaluation.

Physical examination may reveal an obvious penetrating trauma from a stab wound to the lower thoracic back, flanks, and upper abdomen, or bullet entry or exit wounds in this area. In stab wounds, the extent of the entrance wound may not accurately reflect the depth of penetration. Blunt trauma to the back, flank, lower thorax, or upper abdomen may result in renal injury. The following findings on physical examination could indicate possible renal involvement:

- haematuria;
- flank pain;
- flank ecchymoses;
- flank abrasions;
- fractured ribs;
- abdominal distension;
- abdominal mass;
- abdominal tenderness.

2.3.2 Recommendations

| Haemodynamic stability should be decided upon admission. | B |
| History should be taken from conscious patients, witnesses and rescue team personnel with regard to the time and setting of the incident. | C |
| Past renal surgery, and known pre-existing renal abnormalities (ureteropelvic junction obstruction, large cysts, lithiasis) should be recorded. | B |
| A thorough examination should be made of the thorax, abdomen, flanks, and back for penetrating wounds. | B |
| Findings on physical examination such as haematuria, flank pain, flank abrasions and ecchymoses, fractured ribs, abdominal tenderness, distension, or mass could indicate possible renal involvement. | B |

2.3.3 Laboratory evaluation

The trauma patient is evaluated by a series of laboratory tests. Urinalysis, haematocrit, and baseline creatinine are the most important tests for evaluating renal trauma.

Urinalysis is considered the basic test in the evaluation of patients with suspected renal trauma. Haematuria
is the presence of an abnormal quantity of red blood cells in the urine and is usually the first indicator of renal injury. Microscopic haematuria in the trauma setting may be defined as greater than 5 red blood cells per high-power field (rbc/hpf), while gross haematuria is demonstrated by urine in which blood is readily visible.

Haematuria is a hallmark sign of renal injury, but is neither sensitive nor specific enough for differentiating minor and major injuries. It does not necessarily correlate with the degree of injury (29). Major renal injury, such as disruption of the ureteropelvic junction, renal pedicle injuries or segmental arterial thrombosis may occur without haematuria (30). In a study by Eastham et al., 9% of patients with stab wounds and resultant proven renal injury did not manifest haematuria (31). Haematuria that is out of proportion to the history of trauma may suggest pre-existing renal pathology (32). A urine dipstick is an acceptably reliable and rapid test to evaluate haematuria. However, some studies have shown false-negative result rates ranging from 3-10% using the dipstick test for haematuria (33).

Serial haematocrit determination is a method of continuous evaluation of the trauma patient. Initial haematocrit in association with vital signs implies the need for emergency resuscitation. The decrease in haematocrit and the requirement for blood transfusions is an indirect sign of the rate of blood loss and, along with the patient’s response to resuscitation, is valuable in the decision-making process.

As most trauma patients are evaluated within 1 hour of injury, creatinine measurement reflects renal function prior to the injury. An increased creatinine usually reflects pre-existing renal pathology.

2.3.4 Recommendations

<table>
<thead>
<tr>
<th>Urine from a patient with suspected renal injury should be inspected grossly and then by dipstick analysis.</th>
<th>GR</th>
</tr>
</thead>
<tbody>
<tr>
<td>Serial haematocrit measurement indicates blood loss. However, until evaluation is complete, it will not be clear whether it is due to renal trauma and/or associated injuries.</td>
<td>B</td>
</tr>
<tr>
<td>Creatinine measurement could highlight patients who had impaired renal function prior to injury.</td>
<td>C</td>
</tr>
</tbody>
</table>

2.3.5 Imaging: criteria for radiographic assessment in adults

Decisions about radiographic imaging in cases of suspected renal trauma are based on the clinical findings and the mechanism of injury. Since the majority of renal injuries are not significant and resolve without any intervention, many attempts have been made to identify which patients could be spared the discomfort, radiation exposure, possible allergic reaction, time, and expense of a radiographic evaluation (34).

Some patients do not require radiographic evaluation following blunt renal trauma. Patients with microscopic haematuria and no shock after blunt trauma have a low likelihood of concealing significant renal injury (35). The indications for radiographic evaluation are gross haematuria, microscopic haematuria and shock, or the presence of major associated injuries (36). However, patients with a history of rapid deceleration injury with clinical indicators of renal trauma or associated injuries also need immediate imaging to rule out ureteral avulsion or renal pedicle injury (12).

Patients with penetrating trauma to the torso have a high incidence of significant renal injuries. If renal injury is clinically suspected on the basis of an entry or exit wound, renal imaging should be performed, regardless of the degree of haematoma (37).

2.3.5.1 Ultrasonography

Ultrasonography (US) is a popular imaging modality in the initial evaluation of abdominal trauma. It provides a quick, non-invasive, low-cost means of detecting peritoneal fluid collections without exposure to radiation (38). However, the usefulness of conventional US in the radiographic evaluation of renal trauma has been widely questioned. Its limitations stem from the difficulty in obtaining good acoustic windows on trauma patients who have sustained numerous associated injuries. The results are also highly dependent on the operator.

Ultrasound scans can detect renal lacerations but cannot definitely assess their depth and extent and do not provide functional information about renal excretion or urine leakage. Despite the drawbacks of the method, US scans can be conveniently used during the primary assessment of renal injuries. During the evaluation of blunt trauma patients, US scans were more sensitive and specific than standard intravenous pyelography (IVP) in minor renal trauma (39). In a study comparing the results of US scans and IVP, the sensitivity of US decreased as the severity of the trauma increased, while that of IVP remained high for all degrees of severity (40).

Another possible role for US may be for serially evaluating stable renal injuries for the resolution of urinomas and retroperitoneal haematomas (41). Ultrasound might be considered suitable for the routine follow-up of renal parenchymal lesions or haematomas in the intensive care unit. Contrast-enhanced sonography is more sensitive than conventional US in the detection of renal injuries. In haemodynamically stable patients, it is
a useful tool in the assessment of blunt injuries (42).

In conclusion, since US scans are used in the triage of patients with blunt abdominal trauma in many centres, they can be helpful in identifying which patients require a more aggressive radiological exploration to obtain a certain diagnosis (43,44). Ultrasound findings do not provide sufficient evidence for a definite answer on the severity of renal injuries.

2.3.5.2 Standard IVP
Standard IVP is no longer the study of choice for the evaluation of renal trauma. In some centres it may be the only study available, in which case IVP should establish the presence or absence of one or both of the kidneys, clearly define the renal parenchyma, and outline the collecting system. In order to stage renal trauma, the IVP should include nephrotomograms, delineate the renal contour, and visualise the excretion of contrast material from both kidneys into the renal pelvis and ureter. Non-visualisation, contour deformity, or extravasation of contrast implies a major renal injury and should prompt further radiological evaluation with CT or, less commonly, angiography if available.

The most significant findings on IVP are non-function and extravasation. Non-function is usually a sign of extensive trauma to the kidney, pedicle injury (vascular avulsion or thrombosis), or a severely shattered kidney. Extravasation of the contrast medium also implies a severe degree of trauma, involving the capsule, parenchyma, and collecting system. Other less reliable signs are delayed excretion, incomplete filling, calyceal distortion, and obscuring of the renal shadow. The sensitivity of IVP is high (> 92%) for all degrees of trauma severity (45).

2.3.5.3 One-shot intraoperative IVP
Unstable patients selected for immediate operative intervention (and thus unable to have a CT scan) should undergo one-shot IVP in the operating theatre. The technique consists of a bolus intravenous injection of 2 mL/kg of radiographic contrast followed by a single plain film taken after 10 minutes. The study is safe, efficient, and of high quality in the majority of cases. It provides important information for decision-making in the critical time of urgent laparotomy concerning the injured kidney, as well as the presence of a normal functioning kidney on the contralateral side (46).

While the majority of experts advocate its use, not all studies have shown one-shot IVP to be necessary. In cases of penetrating abdominal trauma, the positive predictive value of one-shot IVP was only 20% (80% of patients with normal one-shot IVP findings had renal injuries not detected by the IVP) (47). One-shot IVP is of no significant value in assessing penetrating abdominal trauma patients who undergo exploratory laparotomy for associated intra-abdominal injuries, and should be reserved only for patients with a flank wound or gross haematuria following penetrating trauma (48).

2.3.5.4 Computed tomography (CT)
Computed tomography is the gold standard method for the radiographic assessment of stable patients with renal trauma. CT is more sensitive and specific than IVP, ultrasonography or angiography. In a retrospective study, the positive rate during evaluation of 298 patients was 96% by CT, 91% by double-dose intravenous IVP and 79% by US (45).

Computed tomography more accurately defines the location of injuries, easily detects contusions and devitalised segments, visualises the entire retroperitoneum and any associated haematomas, and simultaneously provides a view of both the abdomen and pelvis. It demonstrates superior anatomical detail, including the depth and location of renal laceration and presence of associated abdominal injuries, and establishes the presence and location of the contralateral kidney (49). Computed tomography is particularly useful in evaluating traumatic injuries to kidneys with pre-existing abnormalities (50).

Intravenous contrast should be administered for renal evaluation. A lack of contrast enhancement of the injured kidney is a hallmark of renal pedicle injury. In cases where this typical finding is not demonstrated, central parahilar haematoma increases the possibility of renal pedicle injury. This sign should be considered even if the renal parenchyma is well enhanced (51).

Renal vein injury remains difficult to diagnose with any type of radiographic study. However, the presence on CT of a large haematoma, medial to the kidney and displacing the renal vasculature, should raise the suspicion of venous injury. Newer ‘spiral’ CT provides shorter scanning time and thus fewer artefacts in the examinations of patients who cannot co-operate adequately (52). Three-dimensional post-processing modalities allow assessment of the renal vascular pedicle by CT angiography and improve the demonstration of complex lacerations of the renal parenchyma. However, injury to the renal collecting system may be missed during routine spiral CT. In all cases of suspected renal trauma evaluated with spiral CT, repeat scans of the kidneys should be performed 10-15 minutes after contrast injection (53). Most blunt ureteral and ureteropelvic junction injuries can be identified if delayed excretory CT scans are performed (54). Computed tomography scanning is also safe as part of the diagnostic procedure for patients with gunshot wounds who are being...
considered for non-operative management (55).

2.3.5.5 Magnetic resonance imaging (MRI)
Although MRI is not used in the majority of renal trauma patients, Leppäniemi et al. investigated the use of high-field strength MRI (1.0 T) in the evaluation of blunt renal trauma (56). MRI scans were accurate in finding peri-renal haematomas, assessing the viability of renal fragments, and detecting pre-existing renal abnormalities, but failed to visualise urinary extravasation on initial examination. The authors concluded that MRI could replace CT in patients with iodine allergy and could be used for initial staging if CT were not available (56).

In a recent study comparing CT and MRI findings, the latter clearly revealed renal fracture with non-viable fragment, and was able to detect focal renal laceration not detected on CT due to peri-renal haematoma (57).

However, MRI is not the first choice in managing patients with trauma because it requires a longer imaging time, increases the cost, and limits access to patients when they are in the magnet during the examination. MRI is therefore useful in renal trauma only if CT is not available, in patients with iodine allergy, or in the very few cases where the findings on CT are equivocal.

2.3.5.6 Angiography
Computed tomography has largely replaced the use of angiography for staging renal injuries, as angiography is less specific, more time-consuming and more invasive. Angiography is, however, more specific for defining the exact location and degree of vascular injuries and may be preferable when planning selective embolisation for the management of persistent or delayed haemorrhage from branching renal vessels (50).

Angiography can define renal lacerations, extravasation, and pedicle injury. Additionally, it is the test of choice for evaluating renal venous injuries. The most common indication for arteriography is non-visualisation of a kidney on IVP after major blunt renal trauma when a CT is not available. Common causes for non-visualisation are:
- total avulsion of the renal vessels (usually presents with life-threatening bleeding);
- renal artery thrombosis;
- severe contusion causing major vascular spasm.

Angiography is also indicated in stable patients to assess pedicle injury if the findings on CT are unclear, and for those who are candidates for radiological control of haemorrhage (31).

2.3.5.7 Radionuclide scans
Radionuclide scans might be helpful for documenting renal blood flow in trauma patients with severe allergy to iodinated contrast material (50), but are not generally used or required.

2.4 Treatment

2.4.1 Indications for renal exploration

The goal in managing patients with renal injuries is to minimise morbidity and to preserve renal function. The need for renal exploration can be predicted with accuracy with a nomogram, which uses the type of injury, transfusion requirements, blood urea nitrogen (BUN), creatinine, and injury grade (58). However, the management of renal injury is usually influenced by the decision to explore or observe associated abdominal injuries (59).

A life-threatening haemodynamic instability due to renal haemorrhage is an absolute indication for renal exploration, irrespective of the mode of injury (60,61). Other indications include an expanding or pulsatile peri-renal haematoma identified at exploratory laparotomy performed for associated injuries (this finding heralds a grade 5 vascular injury and is quite rare). A one-shot intraoperative IVP can provide valuable information. Poor visualisation or any other abnormality of the injured kidney is an indication for exploration.

Grade 5 vascular renal injuries are, by definition, regarded as an absolute indication for exploration, although a single report has suggested that patients who are haemodynamically stable at presentation but with a grade 5 parenchymal injury (shattered kidney) after blunt trauma might be safely treated conservatively (62).

The management of major renal injuries with urinary extravasation and devitalised fragments is controversial. Since these injuries are very uncommon, published series report on small numbers of patients. In recent years, it seems to have been recognised that most major injuries heal with non-operative treatment (63). Moudouni et al. suggest that an initially conservative approach is feasible in stable patients with devitalised fragments (64). These injuries are, however, associated with an increased rate of complications and late surgery (65).

Persistent extravasation or urinoma are usually managed successfully with endourological techniques. Inconclusive renal imaging and a pre-existing renal abnormality or an incidentally diagnosed tumour could require surgery even after relatively minor renal injury (32).

2.4.2 Operative findings and reconstruction

The overall exploration rate for blunt trauma is less than 10% (60), and may be even lower as more centres adopt a very conservative approach to the management of these patients (66). The goal of renal exploration following renal trauma is control of haemorrhage and renal salvage. Most experienced authors suggest the transperitoneal approach for surgery (67,68). Access to the renal vascular pedicle is then obtained through the posterior parietal peritoneum, which is incised over the aorta, just medial to the inferior mesenteric vein.

Temporary vascular occlusion before opening Gerota’s fascia is a safe and effective method during exploration and renal reconstruction (69). It tends to lower blood loss and the nephrectomy rate, and appears not to increase post-operative azotaemia or mortality (70). Renal reconstruction is feasible in most cases. The overall rate of patients who have a nephrectomy during exploration is around 13%, usually in patients with penetrating injury, and higher rates of transfusion requirements, haemodynamic instability, injury severity scores, and mortality (71). Other intra-abdominal injuries also slightly increase the need for nephrectomy (72).

Mortality is associated with the overall severity of the injury and is not often a consequence of the renal injury itself (73). In gunshot injuries caused by a high-velocity bullet, reconstruction can be difficult and nephrectomy is often required (14).

Renorrhaphy is the most common reconstructive technique. Partial nephrectomy is required when non-viable tissue is detected. Watertight closure of the collecting system, if open, might be desirable, although some experts merely close the parenchyma over the injured collecting system with good results. If the renal capsule is not preserved, an omental pedicle flap or peri-reneal fat bolster may be used for coverage (74).

In a review by Shekarriz and Stoller, the use of fibrin sealant in traumatic renal reconstruction proved to be helpful (75). Newly developed haemostatic agents that have proven useful in open and laparoscopic partial nephrectomy, might also be helpful, but are largely unproven in the trauma setting. In all cases, drainage of the ipsilateral retroperitoneum is recommended to provide an outlet for any temporary leakage of urine.

Renovascular injuries are uncommon. They are associated with extensive associated trauma and increased peri- and post-operative mortality and morbidity. Blunt renal artery injury is rare. Non-operative management should be considered as an acceptable therapeutic option (76).

Following blunt trauma, repair of grade 5 vascular injury is seldom if ever effective (77). Repair could be attempted in those very rare cases in which there is a solitary kidney or the patient has sustained bilateral injuries (78). In all other cases, nephrectomy appears to be the treatment of choice (79). In a recent review, it appears that nephrectomy for main renal artery injury has outcomes similar to those of vascular repair, and it does not worsen post-treatment renal function in the short term. Non-operative management for segmental renal artery injury results in excellent outcomes (80).

Angiography with selective renal embolisation for haemorrhage control is a reasonable alternative to laparotomy provided that no other indication for immediate surgery exists (81). Cure of haematuria after superselective transarterial embolisation is reported as high as 98% (82). Successful haemostasis by
Embolisation is reported to be identical in blunt and penetrating injuries (83,84). The complication rate is minimal, and it has been proven effective for grade 4 injuries where conservative therapy failed (85). In our series, embolisation failed when applied to grade 5 injuries (85).

2.4.3 Non-operative management of renal injuries
As the indications for renal exploration become clearer, non-operative management has become the treatment of choice for the majority of renal injuries. In stable patients, supportive care with bed-rest, hydration, and antibiotics is the preferred initial approach (7). Primary conservative management is associated with a lower rate of nephrectomy without any increase in the immediate or long-term morbidity (86). The failure of conservative therapy is low (1.1%) (6).

All grade 1 and 2 renal injuries can be managed non-operatively, whether due to blunt or penetrating trauma. Therapy of grade 3 injuries has been controversial, but recent studies support expectant treatment (87-89). Patients diagnosed with urinary extravasation in solitary injuries can be managed without major intervention and a resolution rate of > 90% (90). Persistent bleeding is the main indication for a reconstruction attempt (91).

The majority of patients with grade 4 and 5 renal injuries present with major associated injuries, and consequently experience high exploration and nephrectomy rates (92), although emerging data indicate that many of these patients can be managed safely with an expectant approach. Although almost all grade 4 patients with penetrating injury require renal exploration, only 20% of those with blunt trauma do (93). Isolated grade 4 renal injuries represent a unique situation to treat the patient based solely on the extent of the renal injury, thus non-operative management is used more frequently. Persistent bleeding represents the main indication for renal exploration and reconstruction. In all cases of severe renal injury, non-operative management should occur only after complete renal staging in haemodynamically stable patients (91).

Penetrating wounds have traditionally been approached surgically. However, stable patients should undergo complete staging to define the full extent of the injury. Renal gunshot injuries should be explored only if they involve the hilum or are accompanied by signs of continued bleeding, ureteral injuries, or renal pelvis lacerations (94).

Low-velocity gunshot and stab wounds of minor degree may be managed conservatively with an acceptably good outcome (95). Tissue damage from high-velocity gunshot injuries, on the other hand, might be more extensive and nephrectomy could be required. Non-operative management of renal gunshot wounds in selected stable patients is associated with a high rate of success (96-98).

If the site of penetration by stab wound is posterior to the anterior axillary line, 88% of such renal injuries can be managed non-operatively (99). Injuries to the flank are more likely to be grade 3, while injuries to the abdomen are more likely to be grade 1. A systematic approach based on clinical, laboratory, and radiological evaluation might minimise negative exploration without increasing morbidity from missed injury (61). Renal stab wounds producing major renal injuries (grade 3 or higher) are more unpredictable and are associated with a higher rate of delayed complications if treated expectantly (100).

2.4.4 Recommendations

| GR | Following grade 1-4 blunt renal trauma, stable patients should be managed conservatively with bed-rest, prophylactic antibiotics, and continuous monitoring of vital signs until haematuria resolves. | B |
| GR | Following grade 1-3 stab and low-velocity gunshot wounds, stable patients, after complete staging, should be selected for expectant management. | B |
| Indications for surgical management include: | - haemodynamic instability; - exploration for associated injuries; - expanding or pulsatile peri-renal haematoma identified during laparotomy; - grade 5 injury. | |
| Incidental finding of pre-existing renal pathology requiring surgical therapy. | B |
| Renal reconstruction should be attempted in cases where the primary goal of controlling haemorrhage is achieved and a sufficient amount of renal parenchyma is viable. | B |

2.4.5 Post-operative care and follow-up
Patients who are successfully treated conservatively carry some risk of complications. This risk correlates with increasing grade. Repeat imaging 2-4 days after trauma minimises the risk of missed complications, especially in grade 3-5 blunt renal injuries (101). However, the utility of frequent CT scanning after injury has never been
satisfactorily proven. CT scans should always be performed on patients with fever, unexplained decreasing haematocrit, or significant flank pain.

Nuclear renal scans are useful for documenting and tracking functional recovery in patients following renal reconstruction before discharge from hospital (97). To detect many of the delayed complications, an excretory urogram is recommended within 3 months of major renal injury, although benefit to the patient has not yet been proven in the literature. Follow-up should involve physical examination, urinalysis, individualised radiological investigation, serial blood pressure measurement and serum determination of renal function (60, 64). Follow-up examinations should continue until healing is documented and laboratory findings have stabilised, although checking for latent renovascular hypertension may need to continue for years (102).

The literature is generally inadequate on the subject of the long-term consequences of trauma on renal tissue. It appears that on histopathological evaluation, renal tissue may appear dystrophic following some cases of conservative management of minor renal injuries (103).

2.4.7 **Complications**

Early complications occur within the first month after injury and can be bleeding, infection, peri-nephric abscess, sepsis, urinary fistula, hypertension, urinary extravasation, and urinoma. Delayed complications include bleeding, hydronephrosis, calculus formation, chronic pyelonephritis, hypertension, arteriovenous fistula, hydrenephrosis, and pseudoaneurysms.

Delayed retroperitoneal bleeding usually occurs within several weeks of an injury or procedure and may be life-threatening. Selective angiographic embolisation is the preferred treatment (104). Peri-nephric abscess formation is usually best managed by percutaneous drainage, although open drainage may sometimes be required (60). Percutaneous management of complications may pose less risk of renal loss than re-operation, which may lead to nephrectomy when infected tissues make reconstruction difficult.

Renal trauma is a rare cause of hypertension, mostly in young men. The frequency of post-traumatic hypertension is estimated to be less than 5% in all published series (105,106). Hypertension may occur acutely as a result of external compression from peri-renal haematoma (Page kidney), or chronically because of compressive scar formation (Goldblatt kidney). Hypertension is usually renin-dependent and associated with parenchymal injury. Renin-mediated hypertension may occur as a long-term complication; aetiologies include renal artery thrombosis, segmental arterial thrombosis, renal artery stenosis (Goldblatt kidney), devitalised fragments and arteriovenous fistulae. Arteriography is informative in cases of post-traumatic hypertension (107). Treatment is required if the hypertension persists, and could include medical management, excision of the ischaemic parenchymal segment, vascular reconstruction, or total nephrectomy (108).

Urinary extravasation after renal reconstruction often subsides without intervention as long as ureteral obstruction and infection are not present. Ureteral retrograde stenting may improve drainage and allow healing (109). Persistent urinary extravasation from an otherwise viable kidney after blunt trauma often responds to stent placement and/or percutaneous drainage as necessary (63).

Arteriovenous fistulae usually present with delayed onset of significant haematuria, most often after penetrating trauma. Percutaneous embolisation is often effective for symptomatic arteriovenous fistulae, but larger ones may require surgery (110).

The development of pseudoaneurysm is a rare complication following blunt renal trauma. In numerous case reports, transcatheter embolisation appears to be a reliable minimally invasive solution (111,112).

Acute renal colic from a retained missile has been reported, and can be managed endoscopically if
possible (113). Other unusual late complications, such as duodenal obstruction, may result from retroperitoneal haematoma following blunt renal trauma (114).

2.4.9 Paediatric renal trauma

Blunt renal trauma is the most common injury seen in children and accounts for more than 90% of renal injuries in the paediatric population (115,116). Children are more susceptible to renal trauma than adults. Differences in anatomy and physiology, as well as the higher incidence of pre-existing renal disease, make children more likely to sustain injury. The kidneys are lower in the abdomen, less well-protected by the lower ribs and muscles of the flank and abdomen, more mobile, have less protective peri-renal fat and are proportionately larger in the abdomen than in adults (117-119).

History and physical examination are very important factors in the evaluation of the paediatric patient with suspected renal trauma. Unlike adults, hypotension is an unreliable sign in children, as an outpouring of catecholamines can maintain blood pressure despite a significant volume of blood loss. Hypotension is less common in children, and significant injury can be present despite stable blood pressures (120). Another important difference from adults is that children with microscopic haematuria or normal urinalyses and stable vital signs may have sustained significant renal injury (121). Haematuria is an important clinical sign of paediatric renal injury and is directly related to the severity of that renal injury and the presence of associated injuries (122).

The radiographic evaluation of children with suspected renal trauma is still controversial. Stein et al. proposed that all paediatric patients with any degree of haematuria should be evaluated for renal trauma (123). In contrast, Morey et al. concluded that significant injuries are unlikely in the absence of gross or significant microscopic haematuria (> 50 rbc/hpf) (124). Nguyen and Das proposed a low threshold for renal imaging following renal trauma. The instances of its use should include patients with blunt abdominal trauma with any level of haematuria, patients with associated abdominal injury regardless of the findings of urinalysis, and patients with normal urinalyses but in whom the mechanism of injury has a high index of suspicion for renal trauma (i.e. rapid deceleration event, direct flank trauma, falls from a height) (125). After studying 720 paediatric trauma cases, Santucci et al. concluded that the decision for imaging based on the adult criteria of gross haematuria, shock and significant deceleration injury is appropriate (126).

Ultrasound is considered a reliable method of screening and following the course of renal injury in paediatric patients with blunt renal trauma in Europe, although it is used much less frequently in the USA (127, 128). Ultrasound is used in some centres, mostly in stable cases with abnormal urinalyses and/or findings suggestive of a major injury (129). The diagnostic accuracy of IVP is superior to that of US, and should be performed as an emergency procedure if CT scan is not available (130).

Computed tomography is the best imaging modality, however, and those with multiple injuries or suspected renal trauma should be evaluated by contrast-enhanced CT if possible (131,132). The use of MRI in paediatric patients with vesicoureteral reflux found that MRI at 1.5 T was better than dimercaptosuccinic acid (DMSA) scans in detecting small renal parenchymal lesions (133), although MRI has little proven use in the acute management of the trauma patient.

Conservative treatment for grade 1-2 renal injuries is clearly defined, and these injuries should be managed expectantly (134). Non-operative management results in an excellent long-term outcome in the majority of cases (135). Non-operative management of high grade renal injuries is effective and is recommended for stable children, but requires close clinical observation, serial CT, and frequent reassessment of the patient’s overall condition (136).

The length of hospital stay does not increase with worsening severity of renal injury, but is determined by the severity of non-renal injuries (137). Haemodynamic instability and a diagnosed grade 5 injury are the strongest indications for operative management (59,120,136). Stable patients with urinary extravasation can also be managed expectantly since most urinomas resolve spontaneously. In cases where there is persistent leakage, the placement of a ureteral stent or percutaneous drainage is feasible and curative in most cases. Early placement of a ureteral stent can be considered for paediatric patients with blunt renal trauma who demonstrate an absence of contrast material in the ipsilateral ureter, as clinical indications for stent placement will likely develop (138).

Major kidney trauma has significant consequences on the opposite side. Post-traumatic functional
evaluation by DMSA scintigraphy 8 days after major injury is a valid prognostic indicator of later function, but its clinical utility has never been established.

Children with renal injuries that fail with non-surgical therapy appear to do so in a median time of 4 hours, but the majority of patients fail within the first 24 hours (139). The failure rate of non-surgical management for renal injuries is 3% (140). Buckley and McAninch presented an algorithm for the management of paediatric renal injuries based on the 25 year experience of the San Francisco General Hospital, which is highly recommended (135) (Figure 1).

Mild renal injuries do not require follow-up imaging. Follow-up is only recommended for patients with major injuries as there is an increased risk of delayed complications and loss of renal function (139).

The majority of patients with severe renal injuries develop parenchymal scars. Radionuclide scans such as DMSA can be useful in the early diagnosis of scars and consequent hypertension (141).

2.4.10 Recommendations

| Indications for radiographic evaluation of children suspected of renal trauma include: |
| 1. blunt and penetrating trauma patients with any level of haematuria; |
| 2. patients with associated abdominal injury regardless of the findings of urinalysis; |
| 3. patients with normal urinalysis who sustained a rapid deceleration event, direct flank trauma, or a fall from a height. |

Ultrasonography is considered a reliable method of screening and monitoring blunt renal injuries by some researchers, but is not universally accepted.

CT scanning is the imaging study of choice for staging renal injuries.

Haemodynamic instability and a diagnosed grade 5 injury are absolute indications for surgical exploration.

2.4.11 Renal injury in the polytrauma patient

Approximately 8-10% of blunt and penetrating abdominal injuries involve the kidneys. The incidence of associated injury in penetrating renal trauma ranges from 77-100%. Gunshot wounds are associated with organ injury more often than are stab wounds. The majority of patients with penetrating renal trauma have associated adjacent organ injuries that may complicate treatment. In the absence of an expanding haematoma with haemodynamic instability, associated multiorgan injuries do not increase the risk of nephrectomy (142).

Blunt and penetrating trauma equally contributed to combined renal and pancreatic injury, as reported by Rosen and McAninch (143). Renal preservation was achieved in most patients, and the complication rate of the series was 15% (143). A similar rate of complications (16%) was reported in patients with simultaneous colon and renal injury. In a report reviewing this combination of injuries over a period of 17 years, 58% of patients underwent an exploration, with nephrectomies performed in 16% of explorations (144).

Renal injuries seem to be rather rare in patients with blunt chest trauma. In a recent study of polytrauma patients, conservative management was safely attempted without increasing morbidity (145). In polytrauma patients undergoing partial or total nephrectomy, there is no increased mortality or renal failure rate (146).

2.4.12 Recommendations

| Polytrauma patients with associated renal injuries should be evaluated on the basis of the most threatening injury. |
| In cases where surgical intervention is chosen, all associated injuries should be evaluated simultaneously. |
| The decision for conservative management should consider all injuries independently. |

2.5 Iatrogenic renal injuries

2.5.1 Iatrogenic vascular injuries

Iatrogenic main renal artery injuries with perforation or rupture are rare. They are usually reported after renal artery angioplasty or stenting, and have an incidence of 1.6% (147). One case of an iatrogenic renal artery perforation as a complication of cardiac catheterisation has also been reported (148). Since most iatrogenic renal artery lesions occur during endovascular procedures, there are no reports on the clinical symptoms, but
only on the angiographic findings. Arteriovenous fistulae, pseudoaneurysms, arterial dissection, or contrast extravasation are the possible radiological findings in these traumatic vascular lesions.

Traditional therapy for renal perforation has been renal artery ligation followed by bypass grafting or nephrectomy, but nowadays the treatment for acute iatrogenic rupture of the main renal artery is balloon tamponade. However, in case of failure, the immediate availability of a stent graft is vital.

Patients with iatrogenic operative injuries are strikingly different from those with penetrating, blunt, or catheter-related vascular trauma. Renal vessels are vulnerable during oncological procedures. Factors that increase technical difficulty are previous operation, tumour recurrence, radiation exposure, and chronic inflammatory changes.

Renal vein injuries during elective abdominal operations represent a serious complication with significant morbidity. Most patients with operative venous injuries have partial lacerations that can be managed with relatively simple techniques, such as venorrhaphy. Patch angioplasty with autologous vein or polytetrafluoroethylene (ePTFE) graft may be required if venorrhaphy is not possible (149).

Some renal vascular injuries, such as pseudoaneurysms following nephron-sparing surgery, can be managed by transcatheter embolisation (150).

2.5.2 Renal transplantation

The orthotopic kidney is protected from external force by muscles, Gerota's fascia, and peri-nephric fat. A renal graft is located in the lower pelvis in the iliac fossa and is therefore more susceptible to injury, especially from direct blows to the abdomen. The transplanted kidney, unlike the native kidney, is fixed in position by a thick fibrotic capsule that develops post-transplant. Also, the transplant kidney is not suspended by the renal vessels, so deceleration events that cause pedicle injury to a native kidney are less likely to affect a transplanted kidney (151). As transplant recipients return to more active lifestyles, including a significant risk of becoming a trauma victim, a renal graft is liable to be severely affected by trauma that might not cause any injury to a native kidney.

In transplant recipients it is very important to know patients' baseline renal function (152). The knowledge of an abnormal renal baseline may prevent unnecessary extensive diagnostic evaluation. Radiographic evaluation should proceed as for the native kidney. The increased risk for contrast nephrotoxicity can be minimised with adequate hydration.

A CT scan is the test of choice for a stable injured transplant recipient, as it will identify renal and associated intra-abdominal injuries and will also indirectly assess renal blood flow and function. A renal duplex examination can be also very helpful for identifying isolated trauma to the transplanted kidney and for identifying renal blood flow. Radionuclide scans might reveal urine leaks and are good for assessing overall blood flow and renal function, while angiography can assess blood flow and identify specific arterial injuries.

The surgical management of an injured transplanted kidney is complex. A very short vascular pedicle and ureter, dense scarring, and a fibrous capsule may prevent any attempt at the direct repair of the parenchymal, collecting system and vascular pedicle injuries. Grade 1-3 injuries can be managed non-operatively. Grade 4-5 injuries might require exploration with debridement and drainage. Major injuries could require a subcapsular nephrectomy. Renovascular injuries have a poor prognosis. Renal arteriography may be helpful with embolisation of the main artery to stop bleeding, or with more selective embolisation to salvage part of the kidney. When renal graft injury occurs, saving the patient's life is the first priority, but saving the graft is also very important to maintain renal function.

Iatrogenic vascular injuries of renal transplants can be managed by embolisation. Angiographic embolisation often fails, and is associated with a high complication rate and high eventual nephrectomy rate (153). On the other hand, transcatheter embolisation is highly effective for biopsy-related vascular injury in the transplanted kidney.

2.5.3 Percutaneous renal procedures

Percutaneous nephrostomy is achieved in nearly all patients without major complications. Haematuria is common for a few days, but massive retroperitoneal haemorrhage is rare. Small subcapsular renal haematomas resolve spontaneously, while arteriovenous-calyceal fistulae are best managed by angiographic embolisation.

If a nephrostomy catheter is seen to transfix the renal pelvis, the possibility of injury to a large renal artery must be considered. The misplaced nephrostomy catheter should be withdrawn over a guidewire, and renal artery embolisation might enable rapid arrest of a life-threatening haemorrhage (154). In more complex cases, CT could be used to detect possible catheter malposition and successfully guide catheter repositioning into the renal collecting system (155).

Renal pelvis injuries can occur during percutaneous nephrostomy placement. Haemorrhage can be prevented by avoiding puncture in anticoagulated or coagulopathic patients, careful puncture on to target calyceals, and avoidance of medial punctures. A pelvic injury is less likely to happen if the dilator is not
advanced further than the calyx, the peelaway sheaths are handled with care, especially when advanced around the pelviureteric junction, and kinking of the guidewires is avoided (156).

Percutaneous renal biopsy is a relatively safe procedure. Haemorrhage, arteriovenous fistula and renal capsular artery pseudoaneurysm might occur. Arteriovenous fistula might present with severe hypertension and is managed by embolisation (157). A pseudoaneurysm should be suspected if the patient presents with flank pain and decreasing haematocrit without haematuria. Arteriography and transarterial embolisation is the appropriate therapy (158).

Percutaneous nephrolithotomy (PCNL) is a popular procedure in which stones in the renal pelvis are removed via a nephroscope, often after ultrasonic or electrohydraulic disruption. The complications include haemorrhage, extravasation, and absorption of large volumes of irrigation fluid, fever, infection, colonic perforation, arteriovenous fistulae, and pneumothorax.

Extravasation of fluid is often due to a tear in the pelvicalyceal system. A close watch on irrigation fluid input and output is required for early recognition of the complication. Termination of the procedure if the renal pelvis is torn or ruptured is a safe choice. Apart from intraoperative evaluation of serum electrolytes, acid-base status and oxygenation, the monitoring of airway pressure is a good indicator of this complication. Metabolic acidosis, hyponatraemia, hypokalaemia, peritonism, and ileus are due to absorption of large volumes of irrigation fluids. Management of this complication requires close monitoring, placement of an abdominal or retroperitoneal drain, correction of acidosis and supportive measures (159).

The diagnosis of a colon injury during or after percutaneous renal surgery can be elusive because symptoms are often variable. An unrecognised or untreated colon injury can result in abscess formation, septicaemia, and/or nephrocolic or colocolonic fistula. Surgical exploration is inevitable when the patient experiences haemorrhage, pneumoperitoneum, and peritonitis.

The majority of these cases can be successfully managed conservatively. The consistent application of proper techniques, avoidance of puncturing the kidney lateral to the posterior axillary line, and puncture of the upper pole calyx when feasible, will help prevent the injuries.

Vascular injuries with renal bleeding are quite frequent and can occur at any stage of the percutaneous procedure, requiring transfusion in 1-11% of cases. A high number of punctures and incorrect choice of puncture site (access that is too medial or direct puncture of the renal pelvis) have been suggested as the cause of vascular lesions after percutaneous procedures. Renal bleeding can arise from both venous and arterial lesions. Bleeding from venous vessels could be profuse at the end of a procedure, but is generally controlled by simple measures, such as placing the patient supine to reduce abdominal compression, positioning a nephrostomy catheter, and forcing diuresis through hydration and parenteral administration of mannitol after clamping of the nephrostomy catheter. In the case of major venous trauma with massive haemorrhage, patients with concomitant renal insufficiency can be treated without open exploration or angiographic embolisation using a Council balloon catheter (160).

Arterial lesions may induce acute or late post-operative bleeding. Severe acute bleeding usually arises from injury to the anterior or posterior segmental arteries. Delayed bleeding is usually caused by interlobar and lower pole artery lesions, often arteriovenous fistulae and post-traumatic aneurysms. Duplex US and CT angiography can diagnose vascular injuries.

Hyperselective renal embolisation is considered the most appropriate technique for the treatment of iatrogenic vascular lesions. It is essential to identify the precise site of the lesion so as to be as selective as possible and reduce the risk of renal dysfunction. Hyperselective catheterisation of the renal artery branches is achieved by means of either hydrophilic 5 French catheters or coaxial systems with low profile microcatheters (2.6 French). The use of an embolic agent helps in performing a distal and irreversible occlusion with complete haemostasis. A variety of embolic materials have been used; microcoils, homologous clots, detachable balloons, polyvinyl alcohol particles, gelfoam, silicone rubber, cotton pellets, and silk filaments. The choice of the embolic agent is dependent mainly on the blood flow entity at the level of the lesion, the vessel size and the operator’s experience.

Finally, complications of endopyelotomy can be classified as major (vascular injury) and minor (infection, urinoma) (161). Preventive steps, along with proper patient selection, minimise the risk for these complications.
2.5.4 **Recommendations**

2.6 **Suggestions for future research studies**

Among the topics that would be useful subjects for future research studies are:

- blunt trauma grade 5 patients, as it appears that some of them may benefit from non-surgical management;
- the necessity and nature of follow-up imaging;
- the value of the administration of antibiotics in low-grade renal injuries selected for conservative management.

2.7 **Algorithms**

Figure 1 is an algorithm for the management of renal trauma in children. Figures 2 and 3 show the suggested treatment of blunt and penetrating renal injuries in adults.

**Figure 1: Algorithm for the management of paediatric renal trauma (119)**
*Suspected renal trauma results from reported mechanism of injury and physical examination.

† Renal imaging: CT scans are the gold standard for evaluating blunt and penetrating renal injuries in stable patients. In settings where the method is not available, the urologist should rely on other imaging modalities (IVP, angiography, radiographic scintigraphy, MRI).

‡ Renal exploration: Although renal salvage is a primary goal for the urologist, decisions concerning the viability of the organ and the type of reconstruction are made during the operation.

3. URETERAL TRAUMA

3.1 Introduction
The ureter is the sole conduit for urinary transport between the kidney and the bladder. Thus, any ureteral injury can threaten the function of the ipsilateral kidney. This small, mobile, worm-like, peristalsing, urothelial-lined tube runs inferiorly from the renal pelvis in the retroperitoneal space. It lies anterior to the muscles of the posterior abdominal wall and lateral to the vertebral column, before descending into the bony ring of the pelvis to enter the bladder. Any external injury to the flank or back and any calamity within the bony pelvis therefore places the ureter at risk. Perhaps because of its protected location, its small size, and its mobility, trauma to the ureter is relatively rare and accounts for only 1% of all urinary tract trauma. Thus, there is a relatively small volume of published clinical experience upon which to base recommendations of management.

3.2 Aetiology

The largest and most contemporary review of ureteral trauma in the European literature is from Dobrowolski et al. in Poland (1). These authors retrospectively analysed the records of patients with upper urinary tract injuries presenting to 61 urology departments between 1995 and 1999. They identified 452 ureteral injuries. Of these, 340 (75%) were iatrogenic, 81 (18%) were from blunt trauma, and 31 (7%) were from penetrating trauma. Of the 340 iatrogenic injuries, 247 (73%) were gynaecological in origin, 46 (14%) were general surgical, and 47 (14%) were urological. It is therefore important to note that ureteral injury is much more likely to occur from activity within a hospital rather than from injuries sustained outside. Dobrowolski et al. estimate the frequency of ureteral injury during gynaecological pelvic surgical procedures to be 1.6 per 1000 (1). Of the total ureteral injuries identified, the injury was in the upper third in 60 cases (13%), in the middle third in 61 cases (13%), and in the lower third in 331 (74%). The median time to diagnosis was 3.3 h.

The most common diagnostic investigation was intravenous urography (IVU), which was used in 244 patients; retrograde ureteropyelography was used in 98 patients; and ureteral catheterisation was used in 125. The diagnosis was also established at open surgery in 104 patients. This snapshot of ureteral trauma in a modern European setting is similar to that seen in the USA (2).
trauma, in which the kidney and renal pelvis can be torn away from the ureter. This deceleration injury is more likely to occur in children because of their hyperextensible vertebral column (4). Haematuria is also a poor indicator of injury, as it is present in only half of those with ureteral trauma (5).

It is possible for isolated ureteral injuries to be missed. Such patients tend to present with subsequent evidence of upper tract obstruction, urinary fistula formation and sepsis (6). After gynaecological pelvic surgery, any woman who complains of flank pain, develops vaginal leakage of urine or becomes septic should also be suspected of having injury to the ureter or bladder and should be investigated appropriately. At surgery, when the ureter is explored to exclude injury, the use of intravenous indigo carmine or methylene blue is to be recommended. This will help reveal the site of injury by leakage of blue-stained urine. This is especially important in partial tears.

### 3.3.2 Radiological diagnosis

Ureteral injury may cause radiological signs of upper urinary tract obstruction but the sine qua non of ureteral injury is extravasation of radiological contrast material (3). This sign can be produced by the use of IVP, giving 2 mg of contrast material per kilogram of body weight. However, because of the increasing use of CT scanning in polytraumatised patients, the diagnosis is increasingly made with this modality.

If a high suspicion of ureteral injury exists and the CT scan is non-diagnostic, then a ‘poor man’s IVP’ can be obtained by taking a plain kidney-ureter-bladder (KUB) film 30 minutes after intravenous injection of CT contrast medium. If this is also non-diagnostic and a suspicion of injury still exists, then retrograde pyelography should be undertaken as the gold standard investigation.

### 3.4 Classification

The AAST has classified ureteral injuries as shown in Table 4 (7).

### 3.5 Management

#### 3.5.1 Partial injuries

These can be defined as grade I to II lesions. Once recognised, they can be managed with ureteral stenting or by placement of a nephrostomy tube to divert urine (3). There is no prospective clinical trial comparing outcomes between these techniques. We believe that ureteral stenting is probably superior because a stent across the injury will allow secure drainage of the kidney, as well as providing canalisation and stabilisation of the injury. We believe that this will reduce the subsequent risk of stricture. The stent may be placed in an antegrade or retrograde fashion. In all cases, fluoroscopy and ureteropyelography with radio-opaque contrast should be used to guide stent placement.

The procedure should commence with the passage of a hydrophilic atraumatic guidewire across the damaged segment of ureter. Once across the site of the injury, an access catheter can be backloaded over the wire and passed across the injury. The hydrophilic wire can then be exchanged for a 0.038-inch wire, and the stent deployed. If this technique is utilised, a bladder catheter should be left in place for 2 days to limit stent reflux during voiding until mucosal healing has begun. The stent should be left in place for at least 3 weeks. The patient should have a follow-up dynamic renogram and IVP between 3 and 6 months, or sooner if lateralising flank pain develops. If there is evidence of stricture, then this should be managed by endourological or open surgical techniques, as appropriate.

If a grade II or III injury is encountered during immediate surgical exploration of an iatrogenic injury, then primary closure of the ureteral ends over a stent may be recommended, with placement of an external, non-suction drain adjacent to the injury.
3.5.2 Complete injuries
These are grade III to V injuries. Successful repair should utilise the principles outlined in Table 5.

Table 5: Principles of repair of complete injury

The type of reconstructive repair procedure chosen by the surgeon depends on the nature and site of the injury (3). The options are depicted in Figure 4.

Figure 4: Diagram of the options for repair of complete injuries, based on the site of the injury

3.5.3 Sterile surgery
3.5.3.1 Uretero-ureterostomy
Using the principles outlined above, the ureteral ends are debrided and freshened. The ends are spatulated. An internal double J-stent is inserted and the ends are closed over the stent using an interrupted 4/0 vicryl suture. An external, non-suction drain is placed at the site of the injury, and a catheter is left in the bladder. The bladder catheter can be removed after 2 days. The wound drain can be removed 2 days later if drainage is low. The stent should be removed after 6 weeks, and a follow-up renogram and IVP should be obtained after 3 months to assess the patency of the repair.

3.5.3.2 Ureterocalycostomy
In cases where the pelvi-ureteral junction has been destroyed, the lower pole of the affected kidney can be amputated to expose the lower pole infundibulum and calyces. The distal ureteral end can then be debrided and spatulated, and anastomosed to the lower pole calyx, over an internal stent, using an interrupted 4/0 vicryl suture. An external, non-suction drain is placed at the site of the injury and a catheter is left in the bladder. The bladder catheter can be removed after 2 days. The wound drain can be removed 2 days later if drainage is low. The stent should be removed after 6 weeks and a follow-up renogram and IVP should be obtained after 3 months to assess the patency of the repair.
3.5.3.3 Transuretero-ureterostomy
The distal end of the injured ureter is ligated with an absorbable suture. The proximal end is debrided and spatulated. This end is then transposed across the midline through a retroperitoneal window above the level of the inferior mesenteric artery. A 1.5 cm ureterotomy is made on the medial aspect of the contralateral ureter. A stent is placed from the ipsilateral kidney, through the anastomosis, and down the distal contralateral ureter into the bladder. A watertight anastomosis is fashioned using an interrupted 4/0 vicryl suture. An external, non-suction drain is placed at the site of the injury, and a catheter is left in the bladder. The bladder catheter can be removed after 2 days. The wound drain can be removed 2 days later if drainage is low. The stent should be removed after 6 weeks, and a follow-up renogram and IVP should be obtained after 3 months to assess the patency of the repair.

3.5.3.4 Ureteroneocystostomy with Boari flap
The proximal ureteral end is debrided and spatulated. A traction suture is placed. The distal ureteral end is ligated with an absorbable suture. The bladder is filled with 200-300 ml of normal saline via a urethral catheter, and controlling stay sutures are placed on the bladder. The L-shaped flap is raised, its base being approximately four times wider than the width of the ureter to be implanted. The ureter is pulled through a submucosal tunnel in the flap and secured to the bladder mucosa using an interrupted 4/0 vicryl suture. Anchoring sutures can be placed at the serosal aspect of the ureter to secure it to the bladder. A stent is placed across the neo-ureterocystostomy, and a suprapubic catheter is placed in the bladder. The bladder is then closed in two layers with 2/0 vicryl sutures. An external, non-suction drain should be placed at the site of the reimplant; it can be removed after 2 days. The urethral catheter can be removed at the same time. The suprapubic catheter can be removed after a cystogram at 2 weeks, and the stent can be removed after 6 weeks. An IVP and renogram should be obtained 3 months thereafter to confirm the patency of the neocystostomy.

3.5.3.5 Ureterocystostomy and psoas hitch
The proximal ureteral end is debrided and spatulated. A traction suture is placed. The distal ureteral end is ligated with an absorbable suture. The fundus of the bladder is mobilised, and the contralateral superior vesical pedicle may be divided to improve fundal mobility. The bladder is filled with 200-300 ml of normal saline via a urethral catheter, and controlling stay sutures are placed. A cystotomy (Blandy) is performed perpendicular to the line of the ureter. Two fingers are placed inside the bladder to stretch it gently towards the ipsilateral psoas tendon. Three non-absorbable 2/0 sutures are placed between the bladder wall and the tendon, with care being taken to avoid the genitofemoral nerve.

Ureteroneocystostomy is then undertaken using either the Leadbetter-Politano or Lich-Gregoire techniques. A double J-stent is placed across the reimplant, and a suprapubic catheter is placed in the bladder. The bladder is then closed in two layers with 2/0 vicryl sutures in the line of the ureter, thus providing extra length to the hitch. The anastomosis is thus under no tension. An external, non-suction drain should be placed at the site of the reimplant, and can be removed after 2 days. The urethral catheter can be removed at the same time. The suprapubic catheter can be removed after a cystogram at 2 weeks, and the stent can be removed after 6 weeks. An IVP and renogram should be obtained 3 months thereafter to confirm the patency of the neocystostomy.

3.5.3.6 Ileal interposition graft
In cases of long segment ureteral destruction, the ureter can be totally replaced using the distal ileum. This should be avoided in patients with coincidental gastrointestinal disease, such as Crohn’s disease, and in patients with impaired renal function. A 25-cm length of ileum is taken out of bowel continuity about 20 cm proximal to the ileocaecal valve. Gastrointestinal continuity is restored with an ileo-ileal anastomosis using interrupted 3/0 seromuscular vicryl. The mesenteric is repaired using 2/0 vicryl. The ileal segment is placed in the isoperistaltic orientation between the renal pelvis and the bladder. Ileo-pelvic and cysto-ileal end-to-end anastomoses are fashioned using 2/0 vicryl. A nephrostomy tube should be inserted into the ipsilateral kidney to decompress the affected upper tract. A catheter should be placed in the bladder. External, non-suction drains should cover the proximal and distal anastomoses. Lastly, the reconstruction should be wrapped in omentum.

The wound drains can be removed after 2 days. A nephrostogram should be performed after 3 weeks; if no leakage is demonstrated, the nephrostomy can be clamped and then removed. Finally, the urinary catheter can be removed. Follow-up should include IVP and renography at 3 months, together with testing for the levels of serum creatinine, chloride, bicarbonate, and base excess, looking for evidence of hyperchloraemic metabolic acidosis.
3.5.3.7 Autotransplantation

If complete ureteral disruption should occur in the presence of coincidental gastrointestinal disease or impaired renal function, then autotransplantation of the affected renal unit can be undertaken. The renal artery and vein are divided long at the aorta and cava. The kidney is moved to the pelvis, and vascular continuity is restored using 5/0 prolene for the artery and 4/0 prolene for the vein. A Lich-Gregoire extravesical neoureterocystostomy can then be fashioned to re-establish urinary drainage. This need not be stented. A covering external, non-suction drain should be placed, and a catheter inserted in the bladder. The drain can be removed after 2 days, if dry, and the catheter removed after a cystogram at 2 weeks. Again, follow-up at 3 months with IVP and renogram is recommended.

3.5.3.8 Nephrectomy

There is one circumstance in which immediate nephrectomy should be undertaken. This is when ureteral injury complicates the repair of an abdominal aortic aneurysm or other vascular procedure in which a vascular prosthesis is to be implanted. We feel that immediate excision of the corrupted renal unit and its damaged ureter leads to less chance of urinary leak, urinoma, sepsis, and graft infection.

4. BLADDER TRAUMA

4.1 Background

Among abdominal injuries that require surgical repair, 2% involve the bladder (1). Blunt or penetrating trauma account for 67-86% and 14-33% of bladder ruptures, respectively (2-4). Motor vehicle accidents are the most common cause (90%) of bladder rupture by blunt trauma (5-7). In the setting of blunt trauma, bladder rupture may be classified as either extraperitoneal with leakage of urine limited to the perivesical space, or intraperitoneal, in which the peritoneal surface has been disrupted, with concomitant urinary extravasation.

Bladder trauma: facts and figures

- 70-97% of patients with bladder injuries caused by blunt trauma have associated pelvic fractures (3,8,9).
- Pubic symphysis diastasis, sacroiliac diastasis, and sacral, iliac, and pubic rami fractures are significantly associated with bladder rupture, whereas isolated acetabular fractures are not (10,11).
- > 50% of the associated pelvic fractures are of the pubic ramus (12).
- Up to 30% of patients with pelvic fractures will have some degree of bladder injury (13).
- Major bladder injury occurs in only 5-10% of patients who have pelvic fracture(s) (7,14).
- > 85% of patients with pelvic fractures have associated injuries in other organ systems (8), with a mortality rate of 22-44% (12,13,15).
- Approximately 25% of intraperitoneal bladder ruptures occur in patients who do not have pelvic fracture(s) (7).
During a motor vehicle accident, traumatic forces can be transferred to the bladder by the seatbelt; injuries usually occur in patients with a full bladder. The degree of distension of the bladder with urine determines its shape and, to some degree, the injury it sustains. A fully distended bladder can be ruptured by a light blow; however, an empty bladder is seldom injured, except by crushing or penetrating wounds. Pelvic scars or pre-existing pelvic pathology can influence susceptibility to injury (16).

Combined intra- and extraperitoneal rupture may occur in 2-20% of cases (7,17-19). Simultaneous bladder and prostate-membranous urethra ruptures occur in 10-29% of male patients (10). Several studies investigating pelvic fractures and associated injuries in paediatric patients reported a lower incidence of urogenital injury (7-14%) (20-23), than in comparative adult series (7,13,14). In seven paediatric series (20-26), the average rate of bladder injury in patients with pelvic fractures was 4%. Motor vehicle accidents were the cause of the trauma in 97% of cases (26).

4.1.1 Iatrogenic trauma

During lower abdominal operations, the bladder is the most frequently injured genitourinary organ (27). Most iatrogenic injuries occur during:

- open abdominal or pelvic surgery (85%);
- anterior vaginal surgery (9%);
- laparoscopy (6%).

The majority (92%) of these injuries are graded as III-IV, using the AAST scale (27). Most injuries occur during obstetric and gynaecological procedures (52-61%), followed by urological (12-39%) and general surgical (9-26%) interventions (27,28). Of the general surgical operations that result in iatrogenic injury to the bladder, most involve resection of bowel as a result of malignancy, diverticulitis, or inflammatory diseases (27,28).

Bladder injury occurs during gynaecological operations in 0.3-8.3% of cases (29-34). Concurrent anti-incontinence surgery significantly increases the risk of injury to the bladder (13% vs 3%; P= 0.049) (34). Most cases of urological iatrogenic trauma occur during vaginal operations and laparoscopy (27,28). The incidence of bladder wall perforation is generally low (1%) during transurethral resection of bladder tumours, and most (88%) can be managed by catheter drainage (35,36). Transurethral resection of the prostate is also associated with low injury rates (37).

Routine cystoscopy is an important adjunct to the major gynaecological procedures, and its omission may result in underestimation of iatrogenic bladder injury. An extensive review of the literature indicated that in studies not involving routine cystoscopy, the frequency of bladder injury varied from 0.2/1000 to 19.5/1000, with an overall frequency of 2.6/1000. Only 52% of bladder injuries were identified and managed intraoperatively (31). In studies involving routine cystoscopy, the frequency of bladder injury varied from 0.0/1000 to 29.2/1000, with an overall frequency of 10.4/1000. Up to 85% of unsuspected bladder injuries were identified with the use of cystoscopy and were managed successfully intraoperatively (31). Routine cystoscopy is recommended after any type of incontinence surgery as it enables identification of unsuspected bladder injury in 85% of patients (31,32,34,38).

Surgical procedures for the correction of stress urinary incontinence can also result in bladder trauma. The rate of bladder injury is below 3% in Burch colposuspension (39-41). Bladder injury is the most common complication of the tension-free vaginal tape (TVT) procedure, with an incidence of 2.0-11.5% (42-47) and up to 19% in patients with prior failed incontinence surgery (48).

The transobturator tape (TOT) procedure minimises the retropubic needle passage, and the incidence of bladder injury is expected to be low. Although during early experience with this technique rates of injury were similar to those associated with the TVT procedure (39), a recent meta-analysis indicated a lower incidence of bladder injuries (odds ratio: 0.12; 95% confidence interval: 0.05-0.33) with TOT procedures (49).

*Advance one grade for multiple injuries up to grade III.

1 Adapted from the AAST.

4.3 Risk factors

Individuals who are driving under the influence of alcohol are likely to have a distended bladder and a motor vehicle accident. Driving after drinking alcohol is therefore a risk factor for bladder injury (19) (LE: 3). Concurrent anti-incontinence surgery during gynaecological procedures results in a fourfold increased risk of bladder injury, and is therefore a risk factor for iatrogenic bladder trauma (34) (LE: 3).

4.4 Diagnosis

The most common signs and symptoms in patients with major bladder injuries are gross haematuria (82%) and abdominal tenderness (62%) (3). Other findings may include inability to void, bruises over the suprapubic region, and abdominal distension (6). Extravasation of urine may result in swelling in the perineum, scrotum, and thighs, as well as along the anterior abdominal wall within the potential space between the transversalis fascia and the parietal peritoneum.

4.4.1 Macroscopic (gross) haematuria

Gross haematuria indicates urological trauma (LE: 3). Traumatic bladder rupture is strongly correlated with the combination of pelvic fracture and gross haematuria. Morey et al. reported gross haematuria in all their patients with bladder rupture, and 85% had pelvic fractures (50). Thus, the classic combination of pelvic fracture and gross haematuria constitutes an absolute indication for immediate cystography in patients who have blunt trauma (3,7,13,50) (LE: 3).

The presence of gross blood at the urethral meatus is diagnostic of a urethral injury (LE: 3). A Foley catheter should not be inserted before a retrograde urethrogram has been carried out to ensure urethral integrity (51). Although grossly clear urine in a trauma patient without a pelvic fracture virtually eliminates the possibility of bladder rupture, 2-10% of patients with bladder rupture may have only microhaematuria or no haematuria at all (5,51).

In a retrospective review of more than 8000 paediatric trauma patients, of those cases with pelvic fractures, only one patient (0.5%) had an extraperitoneal bladder rupture (26). Lower urogenital injury occurred in six patients (2.8%). The absence of gross haematuria ruled out serious injury in this cohort.

Based on this data, no further work-up was recommended in paediatric patients with pelvic fractures without gross haematuria. It is recommended that patients with gross haematuria, multiple associated injuries, or significant abnormalities found on physical examination should be further evaluated with retrograde urethrography and cystography (LE: 3).

4.4.2 Microscopic haematuria

In the trauma patient with a pelvic ring fracture, microscopic haematuria might indicate bladder laceration, and further investigation is warranted (LE: 3). However, the exact quantity of blood in the urine that should trigger investigation is controversial.

• Morgan et al. reported that no ruptures were seen in patients with < 25 red blood cells/high-power field (rbc/hpf) (10).
• Werkman et al. (52) concluded that if cystography had been restricted to patients with > 35-50 rbc/hpf, no perforation would have been missed in their series.
• Fuhrman et al. (53) believe that cystography in blunt trauma should be restricted to patients with gross haematuria, which they defined as > 200 rbc/hpf. They also thought that a retrograde urethrogram should be carried out first.
Existing data do not support lower urinary tract imaging in all patients with pelvic fracture or microscopic haematuria alone. Hochberg and Stone (54) concluded that cystography might be safely reserved for those patients with pelvic fracture considered to be high risk for bladder injury (significant pubic arch involvement, gross haematuria and/or haemodynamic instability), as 90% of patients in their series with pelvic fracture did not have a bladder rupture.

These observations do not appear to be valid for paediatric trauma patients. Abou-Jaoude et al. (55) reported a threshold for radiological evaluation of $\geq 20$ rbc/hpf would miss 25% of cases with bladder injury. In contrast with other reported series (26), they suggested that lower urogenital tract evaluation in paediatric trauma patients, especially in the presence of pelvic fractures, should be based as much on clinical judgment as on the presence of haematuria (55) (LE: 3).

4.4.3 **Cystography**

Retrograde cystography is the standard diagnostic procedure in the evaluation of bladder trauma (7,13,56-58) (LE: 3). This is the most accurate radiological study to identify bladder rupture. When bladder filling and post-void images are obtained, cystography has an accuracy rate of 85-100% (5,7,59,60). Bladder rupture is usually diagnosed when the contrast is identified outside the bladder. Adequate distension of the urinary bladder is crucial to demonstrating perforation, especially in cases of penetrating trauma, as most instances of a false-negative retrograde cystography were found in this situation (56).

Cystography requires plain film, filled film, and post-drainage films (as a minimum) (LE: 3); half-filled film and obliques are optional. For the highest diagnostic accuracy, the bladder must be distended using instillation of at least 350 mL of contrast medium by gravity. Bladder injury may be identified only on the post-drainage film in approximately 10% of cases (7). False-negative findings may result from incorrectly performed studies with less than 250 mL of contrast instillation or omission of a post-drainage film (61) (LE: 3). Only a correctly performed cystography should be used to exclude bladder injury (7).

4.4.4 **Excretory urography IVP**

An IVP is inadequate for evaluation of the bladder and urethra after trauma, not only because of dilution of the contrast material within the bladder, but also because resting intravesical pressure is simply too low to demonstrate a small tear (16,62). An IVP has a low accuracy (15-25%) (15), and clinical studies have indicated that IVP has an unacceptably high false-negative rate (64-84%), which precludes its use as a diagnostic tool in bladder injuries (52,59,63) (LE: 3).

4.4.5 **Ultrasound (US)**

Although, the use of US in bladder rupture has been described (64), it is not routine for evaluation of bladder injury. Free peritoneal fluid in the presence of normal viscera, or failure to visualise the bladder after transurethral saline instillation, are highly suggestive of bladder rupture (66) (LE: 3). Practically, however, US is not definitive in bladder or urethral trauma and is almost never used.

4.4.6 **Computed tomography (CT)**

Computed tomography is clearly the method of choice for the evaluation of patients with blunt or penetrating abdominal and/or pelvic trauma (LE: 3). However, routine CT is not reliable in the diagnosis of bladder rupture, even if an inserted urethral catheter is clamped. CT demonstrates intraperitoneal and extraperitoneal fluid, but cannot differentiate urine from ascites.

As with IVP, the bladder is usually inadequately distended to reveal extravasation through a bladder laceration or perforation during routine abdominal and pelvic studies. Thus, a negative study cannot be entirely trusted, and routine CT cannot exclude bladder injury (12,16,65).

In a review of the cystograms and CT scans (CT cystography) of 25 patients who underwent both investigations during the initial evaluation of blunt abdominal trauma, five patients were found to have bladder rupture, three of which were extraperitoneal and two intraperitoneal (66); all of the injuries were detected by both studies. It was concluded that delayed imaging or contrast instillation could provide the adequate bladder distention needed to demonstrate contrast extravasation from the injury site. Similarly, in a series of 316 patients, 44 cases were diagnosed with bladder ruptures (60). In patients who underwent a formal surgical repair, 82% had operative findings that exactly matched the CT cystography interpretation. Either retrograde cystography or CT cystography are diagnostic procedures of choice for suspected bladder injury (51).

Computed tomography cystography can be used in place of conventional cystography (overall sensitivity 95% and specificity 100%) (LE: 3), especially in patients undergoing CT scanning for other associated injuries (60). However, this procedure should be performed using retrograde filling of the bladder with a minimum of 350 mL of dilute contrast material (7,66,67).

In conclusion, CT cystographic features may lead to accurate classification of bladder injury and allow prompt, effective treatment without further radiation exposure and the additional cost of conventional cystography (70) (LE: 3).
4.4.7 Angiography
Angiography is seldom, if ever, indicated. It can be useful in identifying an occult source of bleeding and can guide its subsequent therapeutic embolisation (16).

4.4.8 Magnetic resonance imaging (MRI)
It is extremely difficult to monitor a seriously injured patient in a strong magnetic field; MRI therefore has little place in the evaluation of acute bladder (16). The use of MRI has been described for later evaluation of urethral injury (69-71).

4.4.9 Cystoscopy
Mainly useful in iatrogenic trauma, routine cystoscopy identifies 85% of the unsuspected injuries to the bladder that would otherwise go unnoticed (31,34,39). Thus, it must be used as an adjunct to major gynaecological operations as well as surgical interventions for incontinence (LE: 3).

4.5 Treatment
The first priority in the treatment of bladder injuries is stabilisation of the patient and treatment of associated life-threatening injuries (LE: 3).

4.5.1 Blunt trauma: extraperitoneal rupture
Most patients with extraperitoneal rupture can be managed safely by catheter drainage alone, even in the presence of extensive retroperitoneal or scrotal extravasation (61) (LE: 3). Obstruction of the catheter by clots or tissue debris must be prevented for healing to occur. A success rate of 90% was reported with this approach in extraperitoneal rupture (5): 87% of the ruptures were healed in 10 days, and virtually all were healed in 3 weeks (57). However, bladder neck involvement (2), the presence of bone fragments in the bladder wall, or entrapment of the bladder wall will necessitate surgical intervention (19) (LE: 3).

4.5.2 Blunt trauma: intraperitoneal rupture
Intraperitoneal ruptures occurring after blunt trauma should always be managed by surgical exploration (LE: 3). This type of injury involves a high degree of force and, because of the severity of associated injuries, carries a high mortality (20-40%) (72). Lacerations are usually large in these cases, with the potential risk of peritonitis due to urine leakage if left untreated (61). Abdominal organs should be inspected for possible associated injuries and urinoma must be drained, if present.

4.5.3 Penetrating injuries
All bladder perforations resulting from penetrating trauma should undergo emergency exploration and repair (61) (LE: 3).

4.5.4 Iatrogenic injuries
Iatrogenic bladder perforations can occur during any pelvic, abdominal, or vaginal procedure (27). Prompt intraoperative recognition is extremely important to ensure a successful repair. Generally, suture repair is satisfactory, limiting unnecessary extravesical dissection (LE: 3). Most (> 95%) of urinary bladder injuries sustained during gynaecological operations are detected and can be managed during surgery (73). Repair can be performed either transvaginally or abdominally. Simple catheter drainage is sufficient in most cases of bladder perforation during transurethral resection of prostate or bladder tumours (36-38) (LE: 3).

5. URETHRAL TRAUMA

5.1 Anatomical and aetiological considerations
The male urethra is divided into the anterior and posterior sections by the urogenital diaphragm. The posterior urethra consists of the prostatic and the membranous urethra. The anterior urethra consists of the bulbar and penile urethra. Only the posterior urethra exists in the female; the anterior urethra corresponds to the labia minora, which results from persistent separation of the urethral folds on the ventral surfaces of the genital tubercle.

5.1.1 Posterior urethral injuries
Road traffic accidents, falls, and crush injuries can cause pelvic fractures, which result in injuries to the posterior urethra. About two-thirds (70%) of pelvic fractures occur because of motor vehicle accidents. The incidence of pelvic fracture is 20% in survivors of motor accidents where fatalities have occurred. The incidence is nearly 50% in fatal pedestrian accidents. Twenty-five per cent of cases result from a fall from a height (1,2).

Altogether, blunt trauma accounts for more than 90% of urethral injuries (3). Overall, the male posterior urethra is injured in 4-19% and the female urethra in 0-6% of all pelvic fractures (2,4-12). The female urethra is rarely injured, except by contusion or laceration by bone fragments.

During crush or deceleration impact injury, the severe shearing forces necessary to fracture the pelvis are transmitted to the prostatomembranous junction, resulting in disruption of the prostate from its connection to the anterior urethra at the prostatic apex. Retrograde urethrography and MRI correlates to this location of the injury (13,14). Cadaveric studies suggest that in most cases the membranous urethra is torn distally to the urogenital diaphragm (15).

An accurate knowledge of the functional anatomy of the sphincter mechanism is essential to the success of posterior urethral surgery. Continence after anastomotic reconstruction of subprostatic pelvic fracture urethral distraction defects depends upon the function of the bladder neck and of the distal urethral sphincter mechanism, each of which is competent and independently capable of maintaining continence in the absence of the other (16).

Unstable pelvic fractures (8,11,17-21), bilateral ischiopubic rami fractures (‘straddle fracture’), and symphysis pubis diastasis have the highest likelihood of injuring the posterior urethra. In particular, the combination of straddle fractures with diastasis of the sacroiliac joint has the highest risk of urethral injury; the odds ratio is about 7 times higher than for either straddle injuries or sacroiliac (‘Malgaigne’) fractures alone (Table 7) (2).

Table 7: Odds ratio of suffering urethral injury with different types of pelvic fracture

Lower urinary tract injury has been reported in about 16% of patients with unilateral rami fractures and in 41% of patients with bilateral rami fractures (22). Anteroposterior compression injuries from frontal crushes produce more severe pelvic fractures, major retroperitoneal bleeding and more frequent injury to the lower urinary tract than do lateral crashes (23).
Prostatomembranous urethral injuries can vary from simple stretching (25%) to partial rupture (25%) or complete disruptions (50%) (2). The more severe injuries result in prostatourethral displacement, with progressive scar formation encompassing the rupture defect. The incidence of double injuries involving the urethra and the bladder ranges between 10% and 20% in males, and may be intraperitoneal (17-39%), extraperitoneal (56-78%), or both (2,7).

Urethral injuries, by themselves, are never life-threatening, except as a consequence of their close association with pelvic fractures and multiple organ injuries, which occur in about 27% of cases. Initially, the assessment and management of other associated injuries is usually more important than the assessment and management of the urethral injury (24).

The American Association for Surgery of Trauma has proposed the classification given in Table 8.

New classifications provide an anatomical classification and a means of comparing treatment strategies and outcomes (26,27). The classification shown in Table 9 combines the best of previous classifications and has direct implications in clinical management.

Clinical management is according to the injury grade:
• grade I no treatment required;
• grades II and III can be managed conservatively with suprapubic cystostomy or urethral catheterisation;
• grades IV and V will require open or endoscopic treatment, primary or delayed;
• grade VI requires primary open repair.
5.1.1.1 Urethral injuries in children
Urethral injuries in children are similar to those in adults. The only significant difference is that straddle pelvic fractures, Malgaigne’s fractures or the association of straddle plus sacroiliac joint fracture is more common in children than in adults. In addition, posterior urethral injuries can involve the prostatic urethra and the bladder neck, as well as the membranous urethra. The tear is often in the prostatic urethra or at the bladder neck because of the rudimentary nature of the prostate, and is more likely to be a complete rupture (69% versus 42%). Urethral stretching is less common than in adults. The more proximal the injury, the greater the risk of incontinence, impotence, and stricture (2,24,28,29).

5.1.1.2 Urethral injuries in women
These are rare events since the female urethra is short and mobile, without any significant attachments to the pubic bone. They usually occur in children. They are often accompanied by severe pelvic fractures, where bony fragments of the fractured pelvis can lacerate the urethra. Urethral injuries in females frequently extend into the bladder neck or vagina, and often disrupt the normal continence mechanism (4,12). Injury to the female urethra is usually a partial tear of the anterior wall and is rarely a complete disruption of the proximal or distal urethra (29).

5.1.1.3 Penetrating injuries to the perineum
These can occur after external violence such as gunshot or stab wounds, or as iatrogenic injuries caused by endoscopic instruments or during surgery for vaginal repair. In developing countries, urethral and bladder neck damage occur quite often as a result of ischaemic injury during obstructed labour.

5.1.2 Anterior urethral injuries
Anterior urethral injuries result from blunt trauma more frequently than from penetrating trauma (Table 10).

5.1.2.1 Blunt trauma
Vehicular accidents, falls, or blows cause most anterior urethral injuries. In contrast to posterior urethral trauma, they are rarely associated with pelvic fractures. They are usually straddle-type injuries caused by blows of blunt objects against the perineum, such as bicycle handlebars or the top of a fence. In this type of accident, the relatively immobile bulbar urethra is trapped and compressed by a direct force on it against the inferior surface of the symphysis pubis. These injuries are more common in children than in adults (28).

5.1.2.2 Intercourse-related trauma
A less common cause of blunt anterior urethral trauma is penile fracture. This rupture of the corpus cavernosum usually occurs during intercourse. In these injuries, the urethra is involved in 20% of the cases (30). Intraluminal stimulation of the urethra with foreign objects has also been reported to cause anterior urethral trauma. Most are short and incomplete, and occur in the distal penile urethra.

Surgery is rarely indicated and depends on the degree and extent of injury to the urethra.
5.1.2.3 Penetrating trauma
Penetrating injuries to the anterior urethra usually result from gunshot wounds and involve the pendulous and bulbar urethral segments equally. These injuries are associated with penile and testicular injury. These can involve the rectum, which may result in pelvic abscesses and the formation of fistulae (31,32). Other less frequent causes of external anterior urethral injuries include stab wounds, penile amputation, and impalement.

5.1.2.4 Constriction band-related trauma
Individuals with paraplegia who use a constriction device for urinary incontinence and forget to release the band because of the lack of sensation can cause severe ischaemic injuries involving the penis and urethra.

5.1.2.5 Iatrogenic trauma
Iatrogenic urethral injuries caused by instruments are by far the most common cause of urethral trauma. Urethral ischaemic injuries related to cardiac bypass procedures are not infrequent and can result in long and fibrotic strictures. A separate section in this chapter discusses iatrogenic trauma in more detail (see section 4.6).

5.2 Diagnosis: initial emergency assessment
5.2.1 Clinical assessment
The initial management of urethral injury is resuscitation of the patient. In the absence of blood at the meatus or genital haematoma, a urological injury is very unlikely and is excluded by catheterisation. Maintain airway and respiratory function, secure the cervical spine if necessary, and address blood loss if present. This is particularly important in posterior urethral injuries because of their close association with pelvic fractures.

The next step includes taking a complete history and carrying out physical, laboratory, and radiographic evaluations in order to identify all injuries accurately. A diagnosis of acute urethral trauma should be suspected from the history. A pelvic fracture, or any external penile or perineal trauma, can be suggestive of urethral trauma (33,34).

For penetrating injuries, the type of weapon used, including the calibre of the bullet, is helpful in assessing potential tissue damage. In a conscious patient, a thorough voiding history should be obtained to establish the time of last urination, the force of the urinary stream, whether urination is painful and whether haematuria is present. The following clinical indicators of acute urethral trauma warrant a complete urethral evaluation.

5.2.1.1 Blood at the meatus
This is present in 37-93% of patients with posterior urethral injury, and in at least 75% of patients with anterior urethral trauma (35,36). When blood is present at the urethral meatus, do not attempt urethral instrumentation until the entire urethra is imaged. In an unstable patient, attempt to pass a urethral catheter, but if there is any difficulty, place a suprapubic catheter and perform a retrograde urethrogram when appropriate.

It is extremely unlikely that gentle passage of a urethral catheter will do any additional damage (37,38), although it has been suggested that this may convert a partial tear into one that is complete (39). There are no convincing data indicating a higher rate of infection or urethral stricture after a single attempt at catheterisation (3). Indeed, if a urethral injury is suspected, urethrography prior to attempted catheterisation is the most prudent approach.

5.2.1.2 Blood at the vaginal introitus
This is present in more than 80% of female patients with pelvic fractures and co-existing urethral injuries (4).

5.2.1.3 Haematuria
Although non-specific, haematuria on a first-voided specimen may indicate urethral injury. The amount of urethral bleeding correlates poorly with the severity of the injury, as a mucosal contusion or small partial tear may be accompanied by copious bleeding, while total transection of the urethra may result in little bleeding (40).

5.2.1.4 Pain on urination or inability to void
The inability to void suggests urethral disruption.

5.2.1.5 Haematoma or swelling
With anterior urethral trauma, the pattern of the haematoma can be useful in identifying the anatomical boundaries violated by the injury. Extravasation of blood or urine in a sleeve distribution along the penile shaft indicates that the injury is confined by Buck’s fascia. Disruption of Buck’s fascia results in a pattern of extravasation limited only by Colles’ fascia, and can extend to the coracoclavicular fascia superiorly and the fascia lata inferiorly. This results in a characteristic butterfly pattern of bruising in the perineum. In female
patients with severe pelvic fractures, the presence of labial swelling may be an indicator of urethral injury. It can be caused by urinary extravasation and warrants immediate attention.

5.2.1.6 High-riding prostate
This is a relatively unreliable finding in the acute phase since the pelvic haematoma associated with pelvic fractures often precludes the adequate palpation of a small prostate, particularly in younger men (3). A boggy mass is usually palpated without recognition of a prostate gland (41). Rectal examination is more important as a tool to screen for rectal injuries, which can be associated with pelvic fractures. Blood on the examination finger is suggestive of a rectal injury. Assessment of concomitant genital injuries is mandatory in every case of external urethral trauma.

5.2.2 Radiographic examination
Retrograde urethrography is the gold standard for evaluating urethral injury (5,29). A scout film should be performed first to assess the radiographic technique, and to detect pelvic fractures and foreign bodies, such as bullets. This is performed using a Foley catheter in the fossa navicularis, with the balloon inflated using 1-2 mL of saline to occlude the urethra. Then, 20-30 mL of contrast material is injected while films are taken in a 30° oblique position. When severe pelvic fractures and associated patient discomfort are present, the oblique position may not always be possible. The radiographic appearance of the urethra permits classification of the injury and facilitates the subsequent management.

If posterior urethral injury is suspected, a suprapubic catheter is inserted. Later on, a simultaneous cystogram and ascending urethrogram can be carried out to assess the site, severity and length of the urethral injury. This is usually done after 3 months if a delayed repair is considered.

When the proximal urethra is not visualised in a simultaneous cystogram and urethrogram, either MRI of the posterior urethra (42) or endoscopy through the suprapubic tract is used to define the anatomy of the posterior urethra. Since manipulation in the bladder can cause the bladder neck to open and give the false impression of incompetence, the endoscopic appearance of the bladder neck should be noted immediately on placing the scope into the bladder (43).

After assessing the endoscopic appearance of the bladder neck, the flexible endoscope can be advanced through the bladder neck into the posterior urethra to the level of obstruction. If there is a question about the length of the distraction, a simultaneous retrograde urethrogram can be performed while the endoscope is in the posterior urethra. The radiographic appearance of the bladder neck is important, but is not as reliable an indicator of continence as the endoscopic appearance is. Furthermore, there are patients who, despite evidence of an open or scarred bladder neck, will have acceptable continence after reconstruction. For this reason, the need for concomitant bladder neck surgery at the time of urethral reconstruction is debatable (43,44).

Ultrasonography is not a routine investigation in the initial assessment of urethral injuries but can be very useful in determining the position of pelvic haematomas, or the exact location of the bladder when a suprapubic catheter is indicated.

Computed tomography and MRI have no place in the initial assessment of urethral injuries. However, they are useful in defining distorted pelvic anatomy after severe injury and assessing associated injuries of penile crura, bladder, kidneys, and intra-abdominal organs (14,45).

5.2.3 Endoscopic examination
Urethroscopy does not have any role in the initial diagnosis of urethral trauma in males. In females, however, where the short urethra precludes adequate retrograde urethrography, urethroscopy is an important adjunct to the physical examination for the identification and staging of urethral injuries (46).

5.3 Management
The management of urethral injuries remains controversial because of the variety of injury patterns, associated injuries and treatment options available. In addition, urethral injuries are relatively uncommon, hence the limited experience of most urologists worldwide and the absence of randomised prospective studies.

5.3.1 Anterior urethral injuries
5.3.1.1 Blunt injuries
Partial tears can be managed with a suprapubic catheter or with urethral catheterisation (29,37,47). Suprapubic cystostomy has the advantage that it not only diverts the urine away from the site of injury, but also avoids urethral manipulation (48), as well as allowing for a simultaneous study to be carried out at a later date.

If the bladder is not easily palpable suprapubically, transabdominal sonography should be used to guide the placement of the catheter. The cystostomy tube is maintained for approximately 4 weeks to allow urethral healing. Voiding cystourethrography is then performed. Remove the suprapubic tube if normal voiding
can be re-established and neither contrast extravasation nor stricture is present.

The potential early complications of acute urethral injuries include strictures and infections. Extravasated blood or urine from the urethral tear produces an inflammatory reaction that can progress to the formation of an abscess. The extent of the infection depends on the fascial planes violated (see section 4.2). The potential sequelae of these infections include urethrocutaneous fistulae, peri-urethral diverticulae and, rarely, necrotising fasciitis. Prompt urinary diversion coupled with the appropriate administration of antibiotics decreases the incidence of these complications.

After the patient has adequately recovered from any associated injuries, and the urethral injury has stabilised, the urethra can be thoroughly re-evaluated radiographically. When necessary, the appropriate reconstructive procedure is planned.

Blunt anterior urethral injuries are associated with spongiosal contusion, which makes it more difficult to evaluate the limits of urethral debridement in the acute phase. Acute or early urethroplasty is therefore not indicated, and the best management is simply suprapubic diversion.

Satisfactory urethral luminal recanalisation occurs in approximately 50% of partial anterior urethral disruptions (47,49). Short and flimsy strictures are managed with optical urethrotomy or urethral dilatation. Denser strictures require formal urethral reconstruction. Anastomotic urethroplasty is indicated in strictures of less than 1 cm in length.

Longer strictures of the anterior urethra should not be repaired by an end-to-end anastomosis, in order to avoid chordee. In these cases, flap urethroplasty is indicated. Almost all complete ruptures of the anterior urethra require anastomotic or patch urethroplasty at 3-6 months. The only exception to this is urethral injury associated with penile fracture; this usually results in partial urethral disruption and can be repaired at the time of cavernosal closure.

5.3.1.2  Open injuries
5.3.1.2.1 Male urethral injuries
Stab wounds, gunshot wounds and dog bites to the urethra often involve the penis and testes and often require immediate exploration. During surgery, the urethral injury can be surgically evaluated and repaired as needed. Urethral strictures form in fewer than 15% of these patients (50).

Primary urethral suturing involves direct visualisation of the severed urethral ends and creation of a watertight, tension-free repair. The patient should be in a supine position. Use a circumferential subcoronal incision to deglove the penis.

In complete disruptions, the corpus spongiosum is mobilised at the level of the injury and the urethral ends dissected distally and proximally. Urethral ends are spatulated, and end-to-end anastomosis is fashioned over a 14 French Foley catheter. Suture small lacerations with fine absorbable material. Careful overclosure of the corpus spongiosum and skin prevents the subsequent formation of fistulae (24). Keep urethral debridement to a minimum since the spongiosum is well vascularised and will usually heal well.

As with any surgery, give pre-operative antimicrobial prophylaxis. Some experts recommend the post-operative continuation of prophylactic antibiotics, but we are not aware of any data that prove that they help. After 10-14 days, obtain a peri-catheter retrograde urethrogram with the urethral catheter in situ. Provided there is no leakage at the anastomotic site, remove the urethral catheter. If there is leakage, leave the catheter in and repeat the cystourethrogram 1 week later.

If the urethra is so extensively disrupted that primary anastomosis is not feasible, then primary repair should be aborted. This occurs with defects of more than 1-1.5 cm in length. One should marsupialise the urethra preparatory to a two-stage urethral repair, and consider a suprapubic urinary diversion. Perform a delayed elective procedure a minimum of 3 months after injury. There is no role for acute placement of a graft or flap in the initial management of any urethral injury, since contamination or decreased blood supply can compromise such a repair (33).

5.3.1.2.2 Female urethral injuries
Most female urethral disruptions can be sutured primarily. These injuries often occur together with bladder ruptures. Frequently, if the bladder injury is going to be repaired primarily, the urethral disruption can be repaired at the same time. For proximal urethral injuries, urethral exposure is best obtained transvesically. Distal urethral injuries can be approached vaginally (29). Early repair of post-traumatic urethral fistulae can also be accomplished transvaginally (4,12).

5.3.2  Posterior urethral injuries
It is important to distinguish between inflammatory or iatrogenic posterior urethral strictures and true pelvic fracture urethral distraction defects as the principles of their surgical management are entirely different. Urethral stricture indicates a narrowing of the urethral lumen. In urethral distraction defects, there is a gap between the two otherwise normal ends of the urethra. The dismembered ends of the urethra retract, and the
space between them fills with fibrous tissue. There is no urethral wall in the scarred space, and any lumen represents merely a fistulous tract between the urethral stumps. A further difference between inflammatory strictures and distraction defects is that the urethral stumps are usually not fibrotic and can be re-anastomosed without tension after distraction injury. Once anastomosed, they usually heal without stricture (51).

Erectile dysfunction occurs in 20-60% of patients after traumatic posterior urethral rupture (51-55). The most important determining factor associated with impotence is the severity of the initial injury. The incidence of erectile dysfunction being caused by the open surgical repair itself is 5% or less (51,56). Erectile dysfunction seems to be a direct result of the pelvic fracture plus urethral injury. King reported an incidence of 42% in cases of pelvic fracture and urethral injury, but only 5% when the urethra was not injured (53). Barbagli et al. reported an incidence of 60% in patients with posterior urethral injury, compared with 14% in patients with bulbar injury (57).

Factors that correlate with the development of impotence are age, defect length, and the type of fracture. Bilateral pubic rami fractures are the most frequent cause of impotence. Impotence is most commonly neurogenic, due to bilateral damage of the cavernous nerves at the prostatomembranous urethra behind the symphysis pubis (58,59). Associated vasculogenic erectile failure may occur in up to 80% of cases (60). Dixon et al. presented evidence that impotence may also be a consequence of avulsion of the corporal cavensum from the ischium (14). In this series, five out of six patients with avulsion of the corpus cavensum off the inferior pubic ramus, were impotent. Spontaneous return of potency may occur up to 2 years after injury (42). Gibson reported an incidence of improved sexual function after 18 months in 21% of patients (52).

5.3.2.1 Partial urethral rupture
Manage partial tears of the posterior urethra with a suprapubic or urethral catheter. Perform urethrography at 2-weekly intervals until healing has occurred (29,37). They may heal without significant scarring or obstruction if managed by diversion alone (48,61). Manage residual or subsequent stricture with urethral dilatation or optical urethrotomy if short and flimsy, and with anastomotic urethroplasty if dense or long (24,37).

5.3.2.2 Complete urethral rupture
Acute treatment options include:
- primary endoscopic realignment;
- immediate open urethroplasty (which should be considered experimental and rarely or never used in patients without associated rectal or bladder neck injury).

Delayed treatment options include:
- ‘delayed primary urethroplasty’ (which implies primary repair 2 weeks after injury and for which there is a lack of supporting evidence in male patients);
- delayed formal urethroplasty at 3 months after injury (the most standard approach);
- delayed endoscopic incision of the scar tissue between the urethral ends (so-called ‘cut-to-the-light’ or similar procedures).

5.3.2.3 Primary realignment
The management of complete posterior rupture of the urethra has changed in recent years. There is now more active orthopaedic management of pelvic fractures with immediate external and internal fixation. This has led to the option of early repair of urethral injuries (37).

In the absence of indications for immediate exploration, posterior urethral disruption can be managed in a delayed primary fashion. Primary realignment requires placement of a suprapubic tube at the time of initial injury, with repair undertaken when the patient is stable, usually within 7 days. At this time, patients are stable, and most pelvic bleeding has resolved. The aim of internal realignment is to correct severe distraction injuries rather than to prevent a stricture occurring, although it will also ensure that it is easily treated if it does occur (62).

Open realignment has been described (63), but it should be performed only in patients who undergo open abdominal or pelvic surgery for associated injuries or internal bone fixation. Haematomas that prevent adequate pelvic descent can be evacuated at this point in these cases.

Concomitant bladder neck or rectal injuries should usually be repaired immediately, and open or endoscopic urethral realignment over a catheter at the same time might be advisable. The reasons for immediate repair of bladder neck and rectal injury are:
1. Unrepaired bladder neck injury risks incontinence and infection of the pelvic fractures.
2. Unrepaired rectal injury carries the obvious risk of sepsis and fistula, and early exploration is indicated to evacuate contaminated haematomas and perform colostomy.
3. Urethral realignment over a stenting catheter is appropriate in such cases (29,40,64-66).

The overall condition of the patient and the extent of the associated injuries greatly affect the decision to proceed with primary realignment. Most patients with pelvic crush injuries have multiple organ injuries.
Associated lower extremity fractures can prevent placement in the lithotomy position, which may be required for primary realignment (although bedside flexible cystoscopy can be used). Head injuries increase the adverse risks of anaesthesia. If these conditions are controlled, such that a haemodynamically stable patient can safely undergo a lengthier anaesthesia and can be placed in the lithotomy position, endoscopic urethral realignment could be considered during the first 2 weeks after trauma.

The proposed benefits of primary alignment are:
1. A lower stricture rate than with suprapubic catheter placement alone (69% versus 10%) (6), which avoids a second operation for urethral reconstruction in about one-third of patients (3).
2. If scarring occurs, restoration of urethral continuity is simplified and may be accomplished by endoscopic procedures or dilatation.
3. If urethroplasty is required later, it is technically easier when the prostate and urethra are well aligned; the disadvantage might be a higher incidence of erectile dysfunction and incontinence when compared with delayed reconstruction (6,67).

The great variation of techniques used for primary realignment procedures confuses any comparison with delayed repair procedures (68-71). Primary realignment techniques include:
- simple passage of a catheter across the defect (70);
- catheter realignment using flexible/rigid endoscopes and biplanar fluoroscopy (72,73);
- use of interlocking sounds ('railroading') or magnetic catheters to place the catheter (71,74);
- pelvic haematoma evacuation and dissection of the prostatic apex (with or without suture anastomosis) over a catheter;
- catheter traction or perineal traction sutures to pull the prostate back to its normal location (75).

Realignment may be insufficient to join the margins of the severed urethra completely, and 1.5-4.0 cm defects have been observed even after catheter realignment (76). This finding agrees with experimental animal data, which show that when the urethra is transacted and an apparently good urethral junction is achieved by catheter traction, there is no evidence of epithelialisation of the mucosal gap, but rather that the intervening area is filled with fibrous tissue (77).

Traction on the catheter might not improve the healing of the urethra, and could in fact harm continence. Sustained traction on the Foley balloon catheter can damage the remaining sphincter mechanism at the bladder neck as a result of pressure necrosis (3,64). Series that use immediate urethral realignment with minimal traction without suture repair bolsters report the most favourable results (Table 11).

Endoscopic primary realignment fulfils these criteria and should be used when a primary procedure is contemplated. Open primary realignment in the absence of bladder neck injury or rectal injury has no place in the treatment of posterior urethral injuries because of its higher morbidity.

5.3.2.4 Immediate open urethroplasty

Immediate open urethroplasty of posterior injuries is not indicated because of poor visualisation and the inability to assess accurately the degree of urethral disruption during the acute phase, characterised by extensive swelling and ecchymosis. The difficulty in identifying structures and planes hampers adequate mobilisation and subsequent surgical apposition (24). Incontinence and impotence rates are higher than with the other techniques described in these guidelines (impotence 56%, incontinence 21%, restructure 49%) (6,29,48,62,65,93,94).

However, in posterior urethral injuries associated with concomitant bladder neck or rectal injuries, immediate open exploration, repair and urethral realignment over a catheter is advisable (29,40,64-66). In children, similar results have been reported with delayed repair and immediate open urethroplasty (63).

5.3.2.5 Delayed primary urethroplasty

Delayed primary urethroplasty is mainly indicated in female urethral disruption, although no large series exists. It requires placement of a suprapubic tube at the time of initial injury, with repair undertaken when the patient is stable, usually within 7 days. Fewer than 50 cases have been reported, and most of these are individual case reports only (12).

Delayed primary repair tries to preserve as much urethral length as possible, and to avoid the urethra becoming embedded in dense scar tissue with consequent incontinence. Surgical exploration should be attempted via the retropubic route for proximal injuries, and the vaginal route for distal injuries (29).

5.3.2.6 Delayed urethroplasty

Delayed urethroplasty is the procedure of choice and the gold standard for the treatment of posterior urethral distraction defects.

Most posterior urethral distraction defects are short, and these can generally be resolved by a perineal approach anastomotic repair, provided that they are not associated with extensive haematoma-fibrosis and the bladder neck mechanism is occlusive and competent. After division of the bulbar urethra at the distal point of obliteration, mobilisation of a normal bulbar urethra to the base of the penis generally achieves 4-5 cm of elastic lengthening. This is usually sufficient to achieve a tension-free 2 cm spatulated overlap anastomosis, after bridging a gap of 2.0-2.5 cm without rerouting (24).

This technique has the advantage that associated injuries, damaged skin and tissues, and pelvic haematoma have resolved by the time it is performed. The only problem with this approach would be the length of time that the patient must have a suprapubic catheter in place before definitive treatment.
When the prostatobulbar gap is longer than 2-3 cm as a result of a high dislocation of the prostate, or when the available elongation of the mobilised urethra has been foreshortened by damage caused by a previous surgical procedure, additional procedures may be required. The following manoeuvres are carried out sequentially to gain sufficient anterior urethral mobility to bridge up to 8 cm of separation, and are referred to as the ‘progressive perineal approach’ (95):

- midline separation of the proximal corporal bodies;
- inferior pubectomy;
- supracorporal urethral rerouting.

In addition to its use as an initial therapy for posterior urethral distraction injuries, the progressive perineal approach can also be applied successfully to salvage procedures following failed repair. There is a number of circumstances that might preclude successful perineal anastomotic repair as either initial or salvage therapy. These circumstances probably represent fewer than 5% of cases and are shown in Table 12 (96,97).

<tr>
<td>Synchronous anterior urethral stricture</td>
<td>The presence of anterior urethral stricture may compromise the blood supply to the bulbar urethra following division of the bulbar arteries, and these patients should be treated cautiously.</td>
</tr>
<tr>
<td>Urinary incontinence</td>
<td>The distal urethral sphincter mechanism could be defunctionalised by urethral distraction, so urinary continence may be maintained primarily by the proximal bladder neck sphincter. Concomitant bladder neck injury might increase incontinence, and could require an abdominoperineal procedure to allow simultaneous bladder neck and urethral reconstruction. The most common cause of bladder neck incompetence is the circumferential tethering of the uninjured bladder neck by scarring. In such cases, it is usually possible to restore functional competence of the bladder neck by mobilising it meticulously. This can be accomplished by removal of the dense haematoma-fibrosis anchoring the bladder neck to the pubis, anteriorly and laterally. Secondary rescarring is prevented by placement of a local omental flap (44, 98).</td>
</tr>
</tbody>
</table>

The results of various techniques are reviewed by Koraitim (66) in a personal series of 100 patients combined with a review of 771 patients from published reports. Immediate and early realignment (n = 326) was associated with rates of 53% for stricture, 5% for incontinence, and 36% for impotence. Of the patients successfully managed with immediate realignment, 42% needed subsequent instrumentation to attempt stabilisation of stricture. Urethroplasty was ultimately necessary in 33%.

Primary suturing (n = 37) was associated with rates of 49% for stricture, 21% for incontinence, and 56% for impotence. In comparison, inserting a suprapubic catheter before delayed repair (n = 508) was associated with rates of 97% for stricture, 4% for incontinence, and 19% for impotence.

The restrict rate after delayed anastomotic urethroplasty was less than 10% (28,38,43,51,55,99-102), and the risk of impotence caused by delayed urethroplasty was about 5% (37,51,55,56,65,103-105).

The gold standard remains delayed urethral repair at a minimum of 3 months after trauma, using a one-stage perineal approach.

The results obtained in children are similar to those in adults. The higher incidence of abdominal surgery simply reflects the greater propensity to damage of the bladder neck in children (105-106).

5.3.2.7 Reconstruction of failed repair of posterior urethral rupture

Restenosis after delayed urethral repair mostly occurs within 6 months. If the anastomosis has a normal calibre at 6 months, then it is extremely unlikely that the patient will develop further stricturing (38).

The principles of salvage repair are similar to those of the initial procedure. Progressive perineal anastomotic repair alone can be successful in 85% of salvage urethroplasties. If an anastomotic repair cannot be performed, a one-stage substitution urethroplasty using a pedicle island of penile skin might be possible.
and could be more desirable than the final alternative, a two-stage scrotourethral inlay procedure or mesh split-thickness skin graft urethroplasty (63,107,108).

The main indications for a combined abdominoperineal surgical approach are:

- the presence of fistulous tracts to the bladder base, abdominal wall or rectum;
- peri-urethral epithelialised cavities;
- an ability to achieve the lithotomy position (97).

Restenosis to a luminal calibre of 12 French Foley catheter or smaller is required before a reduction in the urinary flow is perceived as abnormal (109). A wide calibre stricture may be observed or gently dilated. Optical urethrotomy is an alternative, particularly for a short, narrow stricture.

5.3.2.8 Delayed endoscopic optical incision

The principles of the procedure were described by Sachse in 1974 (109). A curved metal sound is passed through the suprapubic cystostomy into the blind-ended proximal urethra. The direct vision urethrotome is inserted into the urethra, and cuts are made towards the sound.

Blandy described a modification of this procedure: suprapubic passage of a cystoscope for transillumination of the thin perineal membrane and transurethral ‘cutting-to-the-light’ with an electrode (110). Today, the cut-to-the-light technique is sometimes carried out using C-arm fluoroscopy for stereotactic guidance. The urethral catheter is left in place for between 1 and 3 weeks, and the suprapubic drainage for an additional 2 weeks to confirm consistent voiding (111).

The results of several small series have been reported and are summarised in Table 13.

*Laser urethrotomy

The procedure is only indicated if the urethral defect is short, the bladder neck is competent and there is minimal displacement of the prostate and proximal bulbous urethra (116). Although immediate restoration of urethral continuity is commonly possible, failure is common. Urethral dilatation, optical urethrotomy, and transurethral resection of stricture will be needed in about 80% of patients. Most repeat urethrotomies are performed in the first year of follow-up.

It should be noted that after failure of the initial urethrotomy, alternative treatments should be
considered, as repeat urethrotomy achieves only temporary improvement (124). Urethral false passage and rectal perforation have been reported (112,116,119). Stents are not currently recommended for patients with strictures following pelvic trauma, as fibrotic tissue tends to grow though into the lumen of the stent (43,125-127).

5.4 Recommendations for treatment: algorithms
The optimal management of patients with prostatomembranous disruptions should not be thought of as delayed repair versus other types of treatment modalities. Each patient should be assessed and managed according to the initial clinical circumstances. It is impractical to suggest that all patients be managed by one single method because of the variability of each case and the severity of associated injuries. The intervention should be guided by the clinical circumstances. The following algorithms are suggested for the treatment of urethral injuries in males and females (Figures 5-7).

Follow-up
5.5 Iatrogenic urethral trauma

5.5.1 Introduction
The most common form of iatrogenic urethral trauma is that caused by instruments. Most of the relevant urethral lesions caused by iatrogenic trauma are strictures. These strictures are of variable location and severity. They often require different management strategies (128,129).

5.5.2 Iatrogenic urethral trauma caused by catheterisation
The majority of iatrogenic lesions are the result of improper or prolonged catheterisation. They are surprisingly common and account for 32% of urethral strictures. Of these, 52% affect the bulbbar and/or prostatic urethra (129) (LE: 3).

Improper insertion of a urethral catheter is a preventable cause of urethral trauma in male patients (130) (LE: 4). The incidence of this type of urethral injury, especially weighed against the total number of urethral catheterisations performed in the same period of time, is difficult to evaluate, and there have been no statistical
data published on this matter so far. However, the risk to an individual patient of a urethral injury caused by improper catheterisation during a hospital stay has been estimated to be 3.2:1000 (129).

Prolonged catheterisation contributes to stricture formation (129). The anterior urethra is primarily affected. The bladder neck is rarely affected (131) (LE: 1b). Iatrogenic urethral injuries can be prevented by the implementation of educational programmes for medical practitioners that are designed to decrease the exposure of patients to catheter-related risk factors (such as prolonged catheterisation and improper catheterisation) (132) (LE: 2b).

5.5.3 **Iatrogenic urethral trauma caused by transurethral surgery**

Transurethral procedures, especially transurethral resection of the prostate (TURP), are the second most common cause of iatrogenic urethral lesions. Electrical dispersion generated by unipolar electric current and direct urethral injury related to the diameter of the instruments used are factors (133) (LE: 1b). Risk factors include:

- large prostate volume;
- the presence of prostate cancer;
- inexperienced surgeon.

Another cause of stricture formation following transurethral procedures is the form of post-operative urinary drainage used. Urethral catheterisation following transurethral procedures such as TURP, and general post-operative urinary drainage with silicone Foley catheters, both result in a higher incidence of stricture development (134) (LE: 1b).

5.5.4 **Iatrogenic urethral trauma related to surgical prostate cancer treatment**

A major source of iatrogenic urethral trauma is the treatment of prostate cancer. Urethral stricture after prostate cancer treatment can occur anywhere from the bladder neck to the meatus. The rate of bladder neck contracture after radical prostatectomy lies between 0.5% and 32%, varying according to the definition of stricture and individual practice (135,136) (LE: 2a).

The incidence of urethral stricture after multiple forms of prostate cancer therapy is determined from the CaPSURE database, a registry of men with biopsy-proven prostate cancer. The incidence varies from 1.1-8.4%, depending on the form of cancer treatment. The risk is highest after radical prostatectomy or brachytherapy plus external beam radiotherapy. Stricture formation after prostatectomy occurred within the first 24 months, whereas onset was delayed after radiation therapy. In a multivariate analysis, the type of primary treatment, age and obesity were found to be significant predictors for stricture development (135) (LE: 2b).

New surgical methods, such as robot-assisted prostatectomy can also cause iatrogenic trauma. In a recent study, bladder neck contracture was found in 2% of these patients. This correlates to the stricture rate found after conventional radical prostatectomy (137) (LE: 2b).

5.5.5 **Iatrogenic urethral trauma related to radiotherapy for prostate cancer treatment**

Prostate brachytherapy (BT), external beam radiotherapy (EBRT), or a combination of the two are options for selected patients as the primary treatment for prostate cancer. Any of these options can cause urinary fistulas, with an incidence of 0.3-3% for patients after BT, and 0.0-0.6% of those treated with EBRT. Most fistulas will involve the rectum (138,139) (LE: 3).

5.5.6 **Iatrogenic urethral trauma related to major abdominal surgery**

Iatrogenic injuries to the urethra can occur after abdominal and pelvic procedures. Pre-procedure bladder catheterisation must be performed to prevent or to reveal these complications (140) (LE: 2).

5.5.7 **Symptoms of iatrogenic urethral injury**

The symptoms of urethral injury caused by improper catheterisation or use of instruments are:

- penile and/or perineal pain (100%);
- urethral bleeding (86%) (4) (LE: 2b).

Failure accurately to diagnose and treat urethral injuries may lead to significant long-term sequelae (141).

5.5.8 **Diagnosis**

The diagnostic investigation of iatrogenic urethral trauma does not differ from that of other urethral injuries.

5.5.9 **Treatment**

Temporary urethral stenting with an indwelling catheter is a good conventional therapeutic option for treating
Acute false passage (142). The placement of a urethral catheter may be impossible, and endoscopic assistance or even placement of a suprapubic tube might be necessary (143) (LE: 3).

Iatrogenic prostatic urethral strictures after radical prostatectomy can be successfully treated by endoscopic management, either by incision or resection. Failure rates can be high, and repeat therapy might be necessary. The alternative is an indwelling catheter, urethral dilatation or open procedures. Open procedures might be required to salvage recurrent cases, but have increased morbidity (144) (LE: 2b).

Conservative treatment in patients with urethral lesions caused by radiotherapy is often ineffective. Major surgery or lifelong suprapubic diversion might ultimately be necessary (138,139) (LE: 3).

Table 14 details the most common causes of stricture, and Figures 8-10 show flow diagrams for the treatment of stricture after urethral injury due to improper insertion of a catheter, radical prostatectomy, and major abdominal surgery or radiotherapy, respectively.

6. GENITAL TRAUMA

6.1 Background
Traumatic injuries to the genitourinary tract are seen in 2-10% of patients admitted to hospitals (1-5). Of these injuries, between one-third and two-thirds of cases are associated with injuries to the external genitalia (1). The
incidence of genital trauma is higher in men than in women, not only because of anatomical differences but also due to increased exposure to violence, the performance of aggressive sports, and a higher incidence of motor vehicle accidents. In addition, an increase in domestic violence has led to an increase in gunshot and stab wounds over the last several years (6-9). Approximately 35% of all gunshot wounds are affiliated with genital injuries (10).

Genitourinary trauma is seen in all age groups, most frequently in males between 15-40 years. However, 5% of patients are less than 10 years old (10). Genitourinary trauma is commonly caused by blunt injuries (80%) but the risk of associated injuries to neighbouring organs (bladder, urethra, vagina, rectum, bowel) after blunt trauma is higher in females than in males.

Penetrating external genital trauma is seen in about 20% with 40-60% of all penetrating genitourinary lesions involving the external genitalia (11-13).

In men, blunt genital trauma frequently occurs unilaterally. Only 1% present as bilateral scrotal or testicular injuries (10). Penetrating scrotal injuries affect both testes in 30% of cases (10,14). In both genders, penetrating genital injuries occur with other associated injuries in 70% of patients.

The accurate diagnosis and treatment of patients with penetrating injuries are of utmost importance. However, it is essential that physicians and nurses treating trauma patients are aware of an increased risk of hepatitis B and/or C infection in this cohort (7). Recently, a 38% infection rate with hepatitis B and/or C was reported in males with penetrating gunshot or stab wounds to the external genitalia (7). This was significantly higher compared to normal population, and exposes emergency staff to an increased risk.

6.2 Pathophysiology

Proper management of genital trauma requires information about the accident, involved persons, animals, vehicles, and weapons order to estimate the injury and potential risk of associated lesions.

6.2.1 Blunt trauma

In males, a direct blow to the erect penis may cause penile fracture. Usually the penis slips out of the vagina and strikes against the symphysis pubis or perineum. This most frequently (60%) occurs during consensual intercourse (15). Penile fracture is caused by rupture of the cavernosal tunica albuginea, and may be associated with subcutaneous haematoma, and lesions of the corpus spongiosum or urethra in 10-22% (16,17).

Due to the thickness of the tunica albuginea in the flaccid state (approximately 2 mm), blunt trauma to the flaccid penis does not usually cause tearing of the tunica. In these cases, only subcutaneous haematoma with intact tunica albuginea may be seen.

Blunt trauma to the scrotum can cause testicular dislocation, testicular rupture and/or subcutaneous scrotal haematoma. Traumatic dislocation of the testicle occurs rarely. It is most common in victims of motor vehicle accidents or auto-pedestrian accidents (18-21). Bilateral dislocation of the testes has been reported in up to 25% of cases (21). It can be classified as:

1. Subcutaneous dislocation with epifascial displacement of the testis;
2. Internal dislocation; in these cases, the testis is positioned in the superficial external inguinal ring, inguinal canal or abdominal cavity.

Testicular rupture is found in approximately 50% of cases of direct blunt scrotal trauma (22). It may occur under intense, traumatic compression of the testis against the inferior pubic ramus or symphysis, resulting in a rupture of the tunica albuginea of the testis. Wasko and Goldstein estimated that a force of approximately 50 kg is necessary to cause testicular rupture (23).

In females, blunt trauma to the vulva is rarely reported. The incidence of traumatic vulvar haematomas after vaginal deliveries has been reported as 1 in 310 deliveries (24). The frequency in non-obstetric vulvar haematomas is even lower, with only individual cases reported (25). Although blunt trauma to the female external genitals is rarely reported, the presence of vulvar haematoma is closely related to an increased risk of associated vaginal, pelvic or abdominal injuries. Goldman et al. reported that blunt injuries of the vulva and vagina were associated with pelvic trauma in 30%, after consensual intercourse in 25%, sexual assault in 20%, and other blunt trauma in 15% (26).

6.2.2 Penetrating trauma

Penetrating trauma to the external genitalia is frequently associated with complex injuries of other organs. In children, penetrating injuries are most frequently seen after straddle-type falls or laceration of genital skin due to falls on sharp objects (10,27).

Increasing civilian violence has led to a rising incidence of stab and/or gunshot injuries associated with injuries of the genitourinary tract. The extent of injuries associated with guns is related to the calibre and velocity of the missile (8). Handguns or pistols range from 0.22 to 0.45 calibre and produce bullet velocities of
200-300 meters/second (m/s). In addition, “magnum” handguns have larger gunpowder loads, and transmit 20-60% more energy than standard handguns due to the higher velocity of the missile. Injuries by rifles cause even more extensive lesions. Rifles have a calibre ranging from 0.17 to 0.460, with bullet velocities up to 1000 m/s.

Missiles with a velocity of approximately 200-300 m/s are considered “low velocity”. These bullets only induce a ‘permanent cavity’. The energy transmitted to the tissue along the projectile path is much less than in high-velocity missiles, so that tissue destruction in low-velocity guns is less extensive (8). High-velocity missiles (velocity of 800-1000 m/s) have an explosive effect with high-energy transmission to the tissue causing a ‘temporary cavity’ in addition to the permanent cavity. Due to the high-energy released, gaseous tissue vapourisation induces extensive damage often associated with life-threatening injuries.

Gunshot wounds are classified as penetrating, perforating or avulsive. Penetrating injuries are caused by low-velocity missiles, with bullets often retained in the tissue or a small, ragged entry wound. Perforating gunshot wounds are frequently seen in low to high-velocity missiles. In these cases, the missile passes through the tissue with a small entry wound, but larger, exit one. Serious injuries are associated with avulsive gunshot wounds caused by high-velocity missiles, with a small entry wound comparable to the calibre but a large tissue defect at the exit wound.

In any penetrating trauma, tetanus vaccination is mandatory and should be given using active (tetanus toxoid booster) and passive immunisation (250 IE human tetanus immunoglobulin) if the patient’s last immunisation was given more than 5 years ago (28). For current recommendations for tetanus vaccination, see information from the Robert Koch Institute, Germany [http://www.rki.de/cln_116/nr_504558/DE/Content/Infekt/Impfen/ImpfunkenA-Z/Tetanus/Tetanus_ImpfenA-Z_ges.html [Articles in German]].

Although animal bites are common, bites injuring the external genital are rare. Wounds are usually minor, but have a risk of wound infection. The most common bacterial infection by a dog bite is *Pasteurella Multicida*, which accounts for up to 50% of infections (28). Other commonly involved organisms are *Escherichia coli*, *Streptococcus viridans*, *Staphylococcus aureus*, *Eikenella corrodens*, *Capnocytophaga canimorsus*, *Veillonella parvula*, *Bacteroides* and *Fusobacterium spp.* (28-30).

The first choice of antibiotics is penicillin-amoxiclavulanic acid followed by doxycycline, cephalosporine or erythromycine for 10-14 days (31–33). After any animal bite, one has to consider the possibility of rabies infection. In cases where rabies is locally present, vaccination must be given to prevent life-threatening infection (34). Besides vaccination, local wound management is an essential part of post-exposure rabies prophylaxis. If rabies infection is suspected, vaccination should be considered in relation to the animal involved, specific nature of the wound and attack (provoked/unprovoked) and the appearance of the animal (aggressive, foam at the mouth). In high risk patients, vaccination with human rabies immunoglobulin and human diploid cell vaccine is recommended (34,35).

Genital bites from humans can rarely occur, but can also become infected. Wound infections in these cases may include *Streptococci*, *Staphylococcus aureus*, *Haemophilus spp.*, *Bacteroides spp.* and other anaerobes. Transmission of viruses (e.g. hepatitis B, hepatitis C, human immunodeficiency virus [HIV]) following human bites is much less common but should be considered especially in risk groups. Since transmission of viral diseases may occur, risk assessment should be made and, if appropriate, hepatitis B vaccine/immunoglobulin and/or HIV post-exposure prophylaxis offered. For further details see Guidelines for the Management of Human Bite Injuries (36).

Wound management should include cleaning with warm running water or disinfectants. Debridement should be conservative, due to the regenerative capacity of genital skin (36). Antibiotic therapy may be considered only in cases with infected wounds using amoxiclavulanic acid as first line therapy, or, alternatively clindamycin.

### 6.3 Risk factors

There are certain sports with an increased risk for genital trauma. Off-road bicycling and motorbike riding, especially on bikes with a dominant petrol tank, accidents from in-line hockey skating and rugby footballers have been associated with blunt testicular trauma (37-40). Any kind of full contact sports, without the use of necessary protective aids, may be associated with genital trauma.

Besides these risk groups, self-mutilation of the external genitalia have also been reported in psychotic patients and transsexuals (29).

### 6.4 Diagnosis

Investigating genital trauma requires information concerning the accident and a thorough history and physical examination, if possible. Trauma to external genitalia at any age may be due to abusive assault. In these cases, the extraordinary emotional situation of the patient must be considered and the privacy of the patient respected. In suspicious cases, a sexual assault forensic exam is necessary. Swabs or vaginal smears should be taken for detection of spermatozoa (27) and local legal protocols followed closely. A thorough history and
examination (in some cases under anaesthesia), photodocumentation, and identification of forensic material may be important. Genital injury is seen frequently (42%) after sexual abuse, and must be considered when such injuries present at any age (41). In a recent report, only 38% of the forensic samples tested positive for an ejaculate and/or sperm. This may be due to delayed presentation or lack of vaginal/anal ejaculation (42-43).

In patients with gunshot wounds to the genitals several pieces of information will be useful: close or far range, calibre and type of weapon. Get a urinalysis. The presence or macro- and or microhaematuria requires a retrograde urethrogram in males (see above Chapter 4, Urethral trauma). In females, flexible or rigid cystoscopy has been recommended to exclude urethral and bladder injury (26,44). In women with genital injuries and blood at the vaginal introitus, further gynaecologic investigation to exclude vaginal injuries (44).

The potential for significant injury should never be discounted in those patients who also may have blood in the vaginal vault from menstruation. Complete vaginal inspection with specula is mandatory. Depending on the nature of the injury, this may require sedation or general anaesthesia to be completed comfortably.

6.4.1 Blunt penile trauma
6.4.1.1 Penile fracture
Penile fracture is associated with a sudden cracking or popping sound, pain and immediate detumescence. Local swelling of the penile shaft develops quickly, due to enlarging haematoma. Bleeding may spread along the fascial layers of the penile shaft and extend to the lower abdominal wall if Buck’s fascia is also ruptured. The rupture of the tunica may be palpable if the hematoma is not too large. Physical exam and history usually confirm the diagnosis, but in rare cases imaging may be required.

Cavernosography or MRI (45-47) can identify lacerations of the tunica albuginea in unclear cases (48). In case of tunical laceration, surgical correction with suturing of the ruptured area is indicated.

6.4.2 Blunt testicular trauma
Testicular rupture is associated with immediate pain, nausea, vomiting, and sometimes fainting. The hemiscrotum is tender, swollen, and ecchymotic. The testis itself may be difficult to palpate. High-resolution, real-time ultrasonography with a high resolution probe (minimum 7.5MHz or higher) should be performed to determine intra- and/or extratesticular haematoma, testicular contusion, or rupture (49-57). In children, scrotal ultrasonography must be performed with a 10-12MHz probe.

The literature is contradictory as to the real usefulness of US over exam alone. Some studies report convincing results with accuracy of 94% (29,49,54,55). Others reported poor specificity (78%) and sensitivity (28%) for differentiation of testicular rupture or haematocele, and accuracy as low as 56% (52).

Colour Doppler-duplex ultrasonography may provide useful information when used to evaluate testicular perfusion. In case of inconclusive scrotal sonography, testicular CT or MRI may be helpful (58). However, these techniques did not specifically increase the detection of testicular rupture. It may be most prudent to surgically explore these equivocal patients. If imaging studies cannot definitively exclude testicular rupture, surgical exploration is indicated.

6.4.3 Blunt female trauma
In females with blunt trauma to the external genitalia, imaging studies of the pelvis with US, CT, or MRI should be performed since additional injuries and extensive intrapelvic haematoma are frequently found (27,44).

6.4.4 Penetrating trauma
In penetrating trauma of the external genital in men, urethrography should be performed in all patients (irrespective of urinalysis). Associated pelvic or abdominal trauma may also require an abdominal CT. CT cystography should be performed in pelvic injuries associate with microhaematuria. In females, the use of diagnostic laparoscopy for identification of intraperitoneal injuries has been reported prior to explorative laparotomy (27). This approach is only reasonable in haemodynamic stable patients, in whom CT cannot exclude presence of associated bowel injuries or significant intra-abdominal bleeding.

6.5 Treatment
6.5.1 Penile trauma
6.5.1.1 Blunt trauma
Subcutaneous haematoma, without associated rupture of the cavernosal tunica albuginea does not require surgical intervention. In these cases, nonsteroidal analgesics and ice-packs are recommended (13).

Benign penile injuries can be distinguished from penile fracture, because fracture is always associated with rapid post-traumatic detumescence. In penile fracture, surgical intervention with closure of the tunica albuginea is recommended. Closure can be obtained by using either absorbable or non-absorbable sutures, with good long-term outcome and protection of potency. Post-operative complications were reported in 9%, including superficial wound infection and impotence in 1.3% (15,59). Conservative management of penile
fracture is not recommended. It increases complications such as penile abscess, missed urethral disruption, penile curvature, and persistent haematoma requiring delayed surgical intervention (59). Late complications after conservative management were fibrosis and angulations in 35% and impotence in up to 62% (15,59).

6.5.1.2 Penetrating trauma
In penetrating penile trauma, surgical exploration and conservative debridement of necrotic tissue is recommended in most severe injuries. Non-operative management is recommended in small superficial injuries with intact Buck’s fascia (13). Even in extended injuries of the penis, primary alignment of the disrupted tissues may allow for acceptable healing because of the robust penile blood supply (29). In extended loss of penile shaft skin, split-thickness grafts can be placed, either acutely or after the wound bed has been prepared by several days of wet/dry dressing changes and infection is under control. McAininch et al. recommended the use of a skin graft thickness of at least 0.015 inch in order to reduce the risk of contraction (29).

6.5.2 Testicular trauma
6.5.2.1 Blunt trauma
Blunt trauma to the scrotum can cause significant haematocoele even without testicular rupture. Conservative management is recommended in haematocoeles smaller than three times the size of the contralateral testis (6).

In large haematocoeles, non-operative management often fails, and often requires delayed surgery (> 3 days). These patients suffer from a higher rate of orchiectomy than acutely-operated patients, even in non-ruptured testsis (10,22,29,60,61).

Early surgical intervention resulted in > 90% preservation of the testis whereas delayed surgery necessitates orchiectomy in 45-55% (22). Additionally, non-operative management is associated with prolonged hospital stays. Large hematocoeles should be treated surgically, irrespective of testicle contusion or rupture. At the very least, the blood-clot should be evacuated from the tunica vaginalis sac to relieve disability and hasten recovery. Patients initially treated nonoperatively may need delayed surgery if they develop infection or undue pain.

In testicular rupture, surgical exploration with excision of necrotic testicular tubules and closure of the tunica albuginea is indicated. This results in a high rate of testicular preservation and normal endocrine function. Traumatic dislocation of the testis is treated by manual replacement and secondary orchidopexy. If primary manual reposition cannot be performed, immediate orchidopexy is indicated.

6.5.2.2 Penetrating trauma
Penetrating injuries to the scrotum require surgical exploration with conservative debridement of non-viable tissue. Depending on the extent of the injury, primary reconstruction of testis and scrotum can be performed in most cases. In complete disruption of the spermatic cord, realignment without vaso-vasostomy may be considered if surgically feasible (62). Staged secondary microsurgical vaso-vasostomy can be performed after rehabilitation, although there are only a few cases reported (62). If there is extensive destruction of the tunica albuginea, mobilisation of a free tunica vaginalis flap can be performed for testicular closure. If the patient is unstable or reconstruction cannot be achieved, orchiectomy is indicated.

Prophylactic antibiotics are recommended by experts after scrotal penetrating trauma, although data to support this approach is lacking. Tetanus prophylaxis is mandatory. Postoperative complications were reported in 8% of patients who underwent testicular repair after penetrating trauma (13).

Extended laceration of scrotal skin requires surgical intervention for skin closure. Due to the elasticity of the scrotum, most defects can be primarily closed, even if the lacerated skin is only minimally attached to scrotum (29). Local wound management with extensive initial wound debridement and washout is important for scrotal convalescence.

6.5.3 Vulvar injuries
Blunt trauma to the vulva is rare and commonly present as a large haematoma. However, in contrast to men, blunt vulvar or perineal trauma may be associated with voiding problems. Bladder catheterisation will usually be required. Vulvar haematomas usually do not require surgical intervention, although they can cause significant blood loss, even requiring red blood cell transfusions. Data are scarce (25-27,44), but in haemodynamically stable women, non-steroidal anti-inflammatory medication and cold packs are used. In massive vulvar haematoma or haemodynamically unstable patients, surgical intervention, lavage and drainage is indicated (63).

Antibiotics are recommended by experts after major vulvar trauma, but data supporting this approach are lacking. It is important to emphasise that vulvar haematoma and/or blood at the vaginal introitus are an indication for vaginal exploration under sedation or general anaesthesia in order to identify possible associated vaginal and/or rectal injuries (44). In case of vulvar laceration, suturing after conservative debridement is indicated. If there are associated injuries to the vagina, these can be repaired immediately by primary suturing.
Additional injuries to the bladder, rectum or bowel may require laparotomy for closure. The rectal injuries may also require colostomy.

7. MASS CASUALTY EVENTS, TRIAGE AND DAMAGE CONTROL

7.1 Definition
A mass casualty event is one in which the number of injured people is significantly higher than the number of healthcare providers available (1). A mass casualty disaster does not therefore necessarily involve a large number of victims, but is related to the disproportion between the number of victims and the size of the medical team available (2,3). There is little published data on how best to handle these events.

7.2 Causes of mass casualty events
Potential mass casualty events include:
• the collapse of buildings or bridges;
• earthquakes;
• floods;
• tsunamis;
• train collisions;
• aircraft catastrophes;
• civilian terrorism.

Most mass injury caused by civilian terrorism is caused by explosions. The combined effects of blast, shrapnel, bomb projectiles, and burns result in multiple penetrating injuries involving several body systems and unpredictable degrees of damage.

7.3 Mechanisms of explosive injury
The mechanism of injury in explosions is divided into three phases:
• Primary blast injury: this is caused by the powerful shock wave that spreads from the site of the explosion. The most commonly injured organs are those containing air (lungs and ears), but any tissue can be damaged by the pressure wave passing through the body. Urogenital injuries as a direct result of primary blast have not been described in survivors of blast injuries.
• Secondary blast injury: this is produced by the debris and projectiles set in motion by the explosion. Penetrating injuries to the urogenital system, as to any organ, have been described.
• Tertiary injury: this occurs when the victim displaced by the blast wave hits a fixed object. An acceleration-deceleration mechanism produces severe injuries to organs, large blood vessels, and bones. Blunt renal, ureteral, and bladder injuries are induced by this mechanism.

The patterns and severity of injury after explosions differ according to the location of the event. Explosions in confined spaces (e.g. buildings or buses) are more devastating than those that occur in open spaces because of amplification of the blast wave by reflection, and structural collapse, which can cause further injury.

7.4 Triage
Triage after mass casualty events is difficult, controversial, and full of difficult ethical and moral questions. Disaster triage requires one to differentiate the few critically injured that can be saved by immediate intervention from the many with non-life-threatening injuries for whom treatment can be delayed.

Triage divides patients into four groups (4,5):
1. Patients with life-threatening injuries that require immediate intervention, presenting with Airway compromise, Breathing failure and/or Circulatory compromise from ongoing external haemorrhage.
2. Patients with severe but non-life-threatening injuries, in whom treatment can be acceptably delayed: major fractures, vascular injuries of the limbs and large soft tissue wounds.
3. ‘Walking wounded’ with minimal injuries.
4. Patients who are so severely injured that treatment would require allocation of resources and time that would deny other, more salvageable patients, timely care. These patients are given minimal or no treatment, and re-evaluated when resources become available. There is no absolute definition for this
group because triage is individualised according to the number and severity of casualties related to the available resources.

Triage contradicts the everyday principles of care, in which the goal is maximal and optimal care for every individual patient. Triage is necessary in mass casualty scenarios because of the need to provide effective treatment to the maximum number of salvageable patients within the limited resources.

7.4.1 Primary triage
Primary triage begins when trained medical teams arrive at the event. It is concerned with the initial stabilisation and rapid evacuation of the prioritised victims to the nearest hospital.

7.4.2 Secondary triage
Secondary triage begins at the medical facility that is receiving the mass casualties. The most experienced trauma surgeon who is not taking part in surgical or resuscitation procedures performs triage.

7.4.3 Re-triage
Re-triage is performed frequently. After all the victims have undergone triage, the senior surgeon repeats triage and reclassifies patients as necessary.

Re-triage is important. It avoids under-triage, which results in serious injury being missed, or over-triage, which results in some patients being assigned for immediate care when in fact they do not have critical injuries.

The surgeon in charge is responsible for directing specialty surgical consultants, including urologists, and assigning them responsibility for specific patients as dictated by the specific injuries.

7.5 Principles of ‘damage control’
Damage control is a prioritised three-phase approach to patients with major injuries (6). The first phase consists of rapid control of haemorrhage, wound contamination, and faecal spillage using simple measures and temporary abdominal closure. The second phase is resuscitation in the intensive care unit (ICU), with the goal of restoring normal temperature, coagulation, perfusion, and oxygenation of tissues. Then, in the third stage, definitive surgery and abdominal wall closure is performed in stable patients.

Damage control is a life-saving strategy for patients with multiple injuries that has been adopted by trauma surgeons as a result of the observation that such patients often die from hypothermia, coagulopathy, and acidosis-induced physiological insults (7-9). In unstable patients, extensive and time-consuming reconstructive procedures could further destabilise the patient beyond recovery.

Identifying those critically injured patients who are candidates for damage control is difficult. The most senior trauma surgeon should make the decisions, in co-operation with other specialist surgeons.

Damage control principles have also been successfully adopted in the context of civilian mass casualty events, military field surgery, and initial treatment in rural areas with long-range transfers (9,10).

7.6 Urological aspects of ‘damage control’
In events involving mass casualties, the principles of triage and damage control are the same. Damage control can theoretically lower the mortality rates by allowing a limited number of qualified personnel to treat more patients.

Urologists are frequently consulted in patients with multiple injuries, and should be familiar with the damage control approach. Damage control is well suited to urological trauma, and should result in more efficient interaction with the trauma team, improved patient survival and lower morbidity.

In fact, because urological surgery is often elective, management of urological trauma has traditionally consisted of temporary measures followed by definitive surgery later on, which meshes well with modern damage control principles (8). It is important to be aware of damage control opportunities, and to maximise the quality of care with creative improvisation.

7.6.1 The urological consultation in the emergency room during mass casualty events
7.6.1.1 Responsibility and primary overall assessment
After primary assessment and triage by the surgeon in charge, a urological consultation might be required for patients triaged to groups 2 (severe but not immediately life-threatening injuries) and 3 (‘walking wounded’ with mild injuries). The urologist might even become primarily responsible for these patients if they are stable and have few other injuries.

It is important to remember that under-triage can happen during a mass casualty event. A complete re-assessment of the patient assigned must therefore be performed, paying attention to the whole body so as to detect previously unnoticed injuries. This assessment should be quick but comprehensive. Conduct a
rapid ABCDE survey (Airway, Breathing, Circulation, Disability or neurological status, Exposure) as dictated by advanced trauma life support (ATLS) principles (3). Urological care should begin only after the patient is cleared for the presence of other injuries.

7.6.1.2 Imaging
Evaluation of patients with penetrating and blunt abdominal or pelvic trauma usually includes imaging procedures such as contrast CT scans or retrograde cystourethrography (11,12). However, when mass casualty protocols are instituted, decisions on care must be made with a minimum of imaging procedures. In those situations, create a unidirectional flow of patients in order to avoid the bottleneck that usually occurs in imaging departments. The ‘normal’ pattern of sending patients for imaging and then returning them to the accident and emergency department for re-evaluation may not be feasible.

7.6.1.3 Primary management
Following initial primary evaluation, there are several possible scenarios:
1. Haemodynamically unstable patients with suspected intra-abdominal bleeding are transferred urgently to the operating theatre without any pre-operative imaging.
2. Stable patients with suspected renal injuries (penetrating trauma to the upper abdomen/flanks/ lower chest, blunt abdominal trauma, and gross haematuria) should have delayed imaging once the protocols of mass casualties are cancelled, or when resources become available. These patients should be transferred to surgical wards and re-evaluated by the urologist as soon as possible.
3. Patients with suspected bladder or urethral injuries (pelvic fractures, high riding prostate on rectal examination, blood at the urethral meatus and/or inability to void) need to undergo imaging of the lower urinary tract, but this is not urgent as these injuries are not considered life-threatening (13).
4. In cases of suspected urethral injuries, the ‘minimal acceptable treatment’ will be one gentle trial of catheterising the bladder or insertion of a suprapubic cystostomy, followed by transfer of the patient to the surgical ward for later evaluation (14).
5. Bladder injuries following blunt or penetrating trauma are usually associated with other severe injuries (15) and thus require a prioritising surgical approach. The first priority in this scenario is the treatment of the associated life-threatening injuries. Bladder drainage is a sufficient first measure, but should be followed by delayed evaluation aiming to obtain accurate diagnosis and to distinguish between intraperitoneal and extraperitoneal bladder rupture.
6. Blunt injuries of the external genitalia are often isolated and can be managed conservatively. On the other hand, penetrating injuries of the genitalia are often associated with injuries of adjacent abdominal organs and haemodynamic instability (7). In mass casualty scenarios, external genital injuries should be operated on only if they have resulted in major haemorrhage. Surgery can be performed in the operating theatre or in a well-equipped shock room in the accident and emergency department. Compression dressings, or clamping/ligation of bleeding vessels are highly efficient manoeuvres that require a minimum of time. When severe haemorrhage is not present, any further diagnostic steps can be postponed. The patient can be transferred to the surgical ward for later re-evaluation followed by delayed reconstruction.

Urological consultations during a mass casualty scenario should be performed according to the following principles:
1. Rule out under-triage by the surgeon in charge, and perform a rapid primary survey of every patient.
2. Avoid unnecessary imaging procedures such as CT scans and retrograde urethography. These procedures should be performed later, after re-evaluation of the patient, and after mass casualty protocols have been suspended.
3. Treat unstable patients who are to have surgery using damage control principles.
4. Stable patients with suspected renal injuries should be transferred to the surgical ward without imaging procedures. Re-evaluate if there is any change in their haemodynamic status, or when possible as dictated by the constraints of the mass casualty event. Patients managed in this delayed fashion should be treated according to traditional trauma management protocols.
5. ‘Minimal acceptable’ procedures should be performed in order to transfer patients to the surgical wards, e.g. suprapubic drainage of the bladder when bladder or urethral injuries are suspected, clamping and ligation of bleeding vessels from wounds to the external genitalia, etc.

7.6.2 The urological consultation in the operating room during mass casualty events
During emergency laparotomy, urologists are usually present in the operating theatre along with the general surgeons.
During mass casualty events, the principle of ‘minimum acceptable intervention’ for the ‘maximum
salvageable outcome’ applies. Procedures should be directed at the rapid control of active bleeding, and management of urinary extravasation by simple diversion measures. Complex and time-consuming reconstructive procedures should be delayed whenever possible.

7.6.2.1 Renal trauma
The ultimate goal of all renal exploration in the setting of major traumatic renal injury is to control life-threatening bleeding and to preserve the maximal amount of viable renal parenchyma (16).

Renal reconstruction might be too time-consuming in the context of an unstable, multiply injured patient, or in the scenario of mass casualties in which the operating theatre should not be occupied by time-consuming reconstructive procedures (17).

Whenever major active haemorrhage of renal origin can be ruled out, it is best not to explore the injured kidney, even if a secondary delayed laparotomy will eventually be needed (18).

In unstable patients, packing the renal fossa with laparotomy pads and transferring the patient to the surgical ICU is best. Later, a planned second-look laparotomy is better than time-consuming reconstruction (19). Alternatively, especially in briskly bleeding patients, speedy nephrectomy may be required.

Haemostatic techniques, many of which were developed for hepatic surgery and splenic trauma, can be used to control renal parenchymal bleeding (20):

- Mattress sutures through the parenchyma (renorrhaphy), similar to the sutures used in extensive hepatorrhaphy (7).
- Packing with dry folded laparotomy pads as described for peri-hepatic tamponade (7).
- Fibrin hemostatic agents, may be used to control bleeding.
- Absorbable mesh kidney bags maintain renal parenchymal fragments in contact with each other and ensure lasting haemostasis (21).
- Urinary extravasation may be ignored during the acute phase; acutely, urine leak will be drained by intraoperatively placed drains; defer ureteral stents or percutaneous nephrostomies.
- The abdomen is temporarily closed with towel clips or other measures.

Following urgent primary exploration, patients should be carefully monitored in an ICU. When they are sufficiently stable, begin radiological assessment of their injuries and plan their definitive operative management accordingly.

Delayed imaging is obtained by CT scan. If the extent of renal injury has not been clearly defined at the initial laparotomy (by choosing not to explore the retroperitoneal haematoma), a CT scan performed before the second laparotomy can help in decision-making. CT allows the existence and function of the contralateral kidney to be documented, the kidney injury to be graded according to traditional protocols, and a clinical plan to be created, which will then determine the selection of operative or non-operative management of the renal trauma, and whether nephrectomy or reconstruction is to be attempted.

In patients who are haemodynamically unstable after the initial acute damage control laparotomy, or in patients with deteriorating haemodynamic parameters (indicating ongoing or delayed bleeding), the management options are angiographic embolisation of the bleeding kidney or re-operation. This decision should be made according to several factors:

- The general status of the patient.
- The presence of associated injuries that have been treated according to damage control principles (bowel injuries, packed liver, or splenic injuries) and that need re-operation irrespective of the renal injury.
- The availability of angiography.

7.6.2.2 Ureteral injuries
Although excellent results can be achieved with acute ureteral reconstruction, the surgery is time-consuming and might not be appropriate in the mass casualty setting.

During mass casualty events, diagnostic procedures such as the intraoperative injection of indigo carmine, intraoperative IVP or retrograde ueretropyelography that are intended to evaluate ureteral injuries should be discouraged.

If a ureteral injury is suspected but not clearly identified, a drain may be left in place. If urine leaks, a nephrostomy tube can be placed post-operatively.

If a partial ureteral tear is identified (less than half circumference) and the ureter looks viable, a double J-stent may be inserted over a guide wire through the tear, and the tear quickly closed with interrupted absorbable stitches.

When complete ureteral injuries are identified, definitive repair should not be performed. Dissection of the
ureteral stumps should be avoided as it interferes with the blood supply. Instead:

- place a single J or 8 French feeding tube into the ureter;
- tie the distal end of the ureter over the tube;
- exteriorise it through a small stab incision;
- tie it to the skin.

The distal ureteral stump does not need to be ligated, and any unnecessary manipulation should be avoided.

Tying off the injured ureteral segment and inserting a percutaneous nephrostomy post-operatively (22,23) is a viable alternative, but is not the procedure of choice.

In rare, selected cases, nephrectomy is required to treat ureteral injury, but only in cases of severe associated injuries of the ipsilateral kidney (24).

Ureteral injuries are rarely life-threatening and should be addressed only after other injuries have been attended to. In an unstable patient, temporary measures to control urine spillage should be performed, for example:

- tying off of the injured ureteral segment and post-operative insertion of percutaneous nephrostomy (15,19);
- placement of a single J or feeding tube into the ureter, tying the distal end of the ureter over the tube and exteriorising it (15,19,23).

Intraoperative placement of a nephrostomy tube is time-consuming and should be avoided (15,19).

7.6.2.3 Bladder injury

Bladder injuries should be classified, when time and resources allow, as extraperitoneal or intraperitoneal. Extraperitoneal injuries can usually be managed with bladder drainage alone. Intraperitoneal injuries require surgical exploration and layered closure of the bladder wall (13). The degree to which penetrating bladder injury can be treated non-surgically is not known. However, non-surgical management of iatrogenic bladder injuries has been reported, and could be effective after penetrating injury (11,19).

7.6.2.3.1 Auxiliary damage control measures

Examples of auxiliary damage control measures that could be applicable include:

- the placement of externalised ureteral stents can provide external urinary drainage in extensive bladder rupture (19);
- packing or arteriography and selective embolisation can be applied in cases of bladder haemorrhage in patients who are unsuitable for urgent pelvic exploration (13,19);
- the placement of a pelvic suction drain for urinary evacuation (19).

7.6.2.4 Urethral injury

Urethral injury of any kind is never life-threatening per se, but the associated injuries might cause haemodynamic instability. The patient is usually seen by the urologist during an operation performed because of the other injuries. In this situation, no matter whether the urethral tear is posterior or anterior, partial or complete, drainage through a suprapubic or urethral catheter should be obtained without prior imaging.

7.6.2.5 Injury of the external genitalia

Traumatic injuries of the external genitalia are much more common in men than in women, probably because of the anatomical differences (11,25). Blunt injuries of the genitalia are usually isolated, and can be managed conservatively. Penetrating injuries of the genitalia are often associated with injuries of adjacent abdominal organs and related haemodynamic instability (12). In mass casualty events, both types of injury should be managed by watchful waiting. Urethral or testicular imaging and surgical exploration should be deferred.

7.6.2.5.1 Temporary damage control measures

Temporary damage control measure that might be applicable include:

- compression dressing of the penis;
- packing of penetrating testicular injuries;
- tampons for vulvar lacerations.

7.7 Summary

- Damage control surgery has become the standard approach in the management of unstable patients, and is especially useful in a mass trauma event.
- Medical teams should be well prepared ahead of time to deal with mass casualty events.
- All surgical sub-specialists involved in trauma management should be very familiar with the principles of triage and damage control.

Conflict of interest

All members of the Urological Trauma Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.
